A literature review of the factors involved in older people’s decision making with regard to influenza vaccination

ABSTRACT

Aims and objectives
By reviewing the relevant literature, the aim of this paper is to develop an understanding of the factors involved in older people’s decision making with regard to influenza vaccination to inform strategies to improve vaccine uptake and reduce morbidity and mortality.

Background
Influenza is a major cause of morbidity and mortality world-wide. In the U.K. it accounts for 3-6000 deaths annually; 85% of these deaths are people aged 65 and over. Despite this, and the widespread and costly annual government campaigns, some older people at risk of influenza and the associated complications remain reluctant to take advantage of the offer of vaccination.

Methods
A review of the English language literature referring to older people and published between 1996 and 2005. Inclusion and exclusion criteria were identified and applied.

Findings
The majority of the literature was quantitative in nature, investigating personal characteristics thought to be predictors of uptake, such as age, sex, co-morbidity, educational level, income and area of residence. However, there was little discussion of the possible reasons for the significance of these factors and conflict between findings was often evident, particularly between studies employing different methodologies. Other factors identified were prior experience, concerns about the vaccine, perceived risk and advice and information.
Relevance to practice
The wealth of demographic information available will be useful at a strategic level in targeting groups identified as being unlikely to accept vaccination. However, the promotion of person-centred ways of working that value the health beliefs, attitudes, perceptions and subjective experiences of older people is likely to be more successful during individual encounters designed to promote acceptance. Without more research investigating these concepts our understanding is inevitably limited.

Keywords
Older people; influenza; vaccination, nurses, nursing, health promotion
INTRODUCTION

Influenza has been described as ‘an invariable disease caused by a variable virus’ (Potter 2001, p.573). It is this variability, the ability of the virus to mutate rapidly and even produce completely new unrelated strains, which allows it to be a continued cause of epidemic and pandemic disease. Historical records allude to possible pandemics as far back as 412BC and there is reliable evidence for the past 300 years (Potter 2001). Pandemics – sudden, unexpected outbreaks in a specific geographical area, subsequently spreading world-wide, infecting millions and causing large numbers of deaths – occur every 10-50 years and are due to new virus strains, a process known as antigenic shift. The majority of the population will have no immunity to these new influenza viruses, resulting in extremely high morbidity and mortality rates. An epidemic – a sudden, unexpected outbreak, infecting a large percentage of the population and disappearing within a few weeks or months – will occur somewhere in the world in most years, and is due to mutation of an existing virus strain, a process know as antigenic drift (Potter 2001). It is this mutation which necessitates annual vaccination.

Influenza is an acute viral illness of the upper respiratory tract, sudden in onset with fever, muscle pain, joint pain, headache, dry cough and malaise and, occasionally, rhinitis (Potter 2001, Riley & Riley 2003). Potter (2001, p.572) differentiates influenza from ‘flu-like illness’ with the phrase ‘a degree of prostration out of all proportion with the severity of other symptoms’. Spread by droplets from the cough or sneeze of an infected person being inhaled by others, it is therefore more common in the U.K. in winter when people tend to congregate in warm, enclosed, poorly ventilated environments. An incubation period of 1 to 4 days precedes the onset of symptoms, with infectivity starting 1 day before and continuing for 7 days after. Recovery may take up to 2 weeks but a prolonged period of post-viral malaise may ensue (Riley & Riley 2003). Of the three identified types of influenza virus, A, B and C, only types A and B cause significant morbidity in humans, type A occurring more frequently and being more virulent (Riley & Riley 2003).
Influenza activity is monitored globally by the World Health Organisation (WHO). The three most virulent strains in circulation are identified and recommended for inclusion in the vaccine for the current year to provide protection against the strains thought likely to cause epidemics that particular year (Liddle & Jennings 2001). In recent years the vaccine strains have closely matched the circulating strains, resulting in high levels of protection.

Up to 20% of the UK population may be affected annually (NHS Centre for Reviews and Dissemination, 1996, available at www.york.ac.uk/inst/crd, accessed 16 May 2005) and between 10-20% of the US population (Goldrick 2004). However, it is not just influenza itself which is a cause for concern - it is the risk of complications arising from secondary infection and the exacerbation of pre-existing conditions. Significant increases in hospital admissions and an estimated 3-6000 deaths annually, 85% of which occur in those aged 65 or over, have been attributed directly or indirectly to influenza (NHS Centre for Reviews and Dissemination 1996; NICE 2003, available at www.nice.org.uk, accessed 16 June 2006). The costs are therefore high in both human and financial terms.

In 2000 the Department of Health recommended annual vaccination for all those in ‘at risk groups’ setting a target of 60% coverage, which has since been raised to 70% (DoH 2003). At risk groups are defined as those:

- aged 65 or over
- with chronic renal disease, including nephrotic syndrome, chronic renal failure and post-transplantation*
- with chronic heart disease, including hypertension with cardiac complications, chronic heart failure and those needing medication and/or follow-up for ischaemic heart disease*
- with chronic respiratory disease, including chronic obstructive pulmonary disease and asthmatic people requiring continuous or repeated inhaled or systemic steroids, or when exacerbations have previously required hospitalisation*
- Chronic liver disease, including cirrhosis*
- with diabetes mellitus, requiring insulin or oral hypoglycaemic drugs*
• with immunosuppression due to disease or treatment*
• living in long-stay facilities such as residential or nursing homes
• who are the main carer of an older or disabled person.

*aged six months or over (DoH 2005).

Immunisation programmes in general are amongst the most effective public health initiatives undertaken and have been credited with saving more lives than any other, with the exception of the provision of clean water (Plotkin & Plotkin 1999). Influenza vaccination is estimated to provide between 60 and 90% protection against infection (Potter 2001), although there is evidence that a diminished immune response in older people may reduce that figure (Gross et al. 1995, Morgan & King 1996). Although ‘immunisation has never made an impact on the course of an (influenza) epidemic’ (Potter 2001, p.573), annual vaccination of all older people has proved to be cost-effective in reducing influenza related illness and death (Govaert et al. 1994, Ohmit & Monto 1995).

Vaccination should take place ideally before the ‘flu season starts, October or early November in the U.K. (NHS Centre for Reviews and Dissemination 1996, Liddle & Jennings 2001). However, later vaccination may still be worthwhile, as an effective immune response has been demonstrated at 10 to 14 days post vaccination (Liddle & Jennings 2001, Riley & Riley 2003). Annual vaccination has been found to have a cumulative effect (NHS Centre for Reviews and Dissemination 1996), there is also evidence that pneumococcal and influenza vaccination have additive effects (Nichol 1999). Despite strong evidence of the safety and efficacy of modern influenza vaccines there is still reluctance among some older people to accept vaccination (NHS Centre for Reviews and Dissemination 1996, Andrew et al. 2004). The effectiveness of any vaccine depends largely on public acceptance (Cameron 1996, Ritvo et al. 2003). This review of the available evidence aims to develop an understanding of the factors involved in the decision to accept or refuse vaccination and may lead to strategies to improve acceptance and therefore, reduce morbidity and mortality.
**SEARCH STRATEGY**

BNI, AMED, CINAHL, HMIC, PsychINFO and Blackwell Synergy were searched electronically and reference lists followed up. Key words used were ‘older people’, ‘elderly people’, ‘influenza vaccination’. Full texts were retrieved electronically or from the British Library via RCN Library Services, where available. The following inclusion and exclusion criteria were identified:

- Age of subjects, 65 years or over.
- English language.
- U.K. studies or those with findings transferable to the U.K. setting.
- Papers that identified and/or discussed the factors involved in uptake of vaccination.
- Papers from peer reviewed journals, where this could be ascertained.

A total of 207 papers were identified, after application of the above criteria 10 remained on which to base this review.

**FINDINGS AND DISCUSSION**

Analysis of these papers revealed recurrent themes and predictors of vaccination acceptance or refusal, which could be broadly grouped into the following categories:

- Demographics
- Prior experience
- Concerns about the vaccine
- Perceived risks
- Advice and information

**Demographics**

Personal characteristics have been studied as a means of predicting influenza vaccination uptake (Honkanen et al. 1996, van Essen et al. 1997, Gosney 2000, O’Reilly et al. 2002, Kamal et al. 2003, Andrew et al. 2004, Nowalk et al. 2004) but findings have not always been consistent.

**Gender**

Quantitative studies in the U.S have found that men are more likely to be vaccinated than women (Kamal et al. 2003, Nowalk et al. 2004), although Kamal et al. (2003) found gender not to be statistically significant. Nowalk
et al. (2004) conducted 557 interviews in a computer-assisted telephone survey of people aged 65 and older, which revealed that 81% of male respondents versus 73% of female respondents had been vaccinated. However, there is no comparison of the age ranges between sexes and as women tend to have a longer life expectancy than men, the female respondents may have been older (Office for National Statistics 2005, available at www.statistics.gov.uk accessed 17 July 2006).

Age
O’Reilly et al. (2002), in an audit of vaccination rates in 12 General Practitioner (GP) Practices in Northern Ireland, found that men between the ages of 75 and 90 were 5% more likely to be vaccinated than women. There is acknowledgement that the Practices audited may not be representative because of high levels of computerisation and generalizability thus is reduced. Again, there is no comparison of the age ranges between sexes so the finding may not be reliable. Andrew et al. (2004) in a quantitative survey of 5,007 community-dwelling adults over 65, without dementia and who responded to a question about influenza vaccination, found that increasing age was positively predictive of vaccination uptake. The sample in this study was drawn from the Canadian Study of Health and Aging, a population-based national cohort study of people aged over 65 conducted in 1991, and not specifically designed for the purpose. Although published in 2004, the data were collected in the early 1990s, therefore the age of the data may mean that the findings do not reflect the current position, but concurrence with other studies would indicate that this is not the case. Self-report is another source of potential bias but again this is asserted to be moderately specific and highly sensitive (Andrew et al. 2004) when compared with medical records. O’Reilly et al. (2002) found this to be true to an extent, up to the age of 85, but that people over 85 were less likely to be vaccinated. They suggested a number of causes for this including: a lack of ability to give informed consent due to cognitive impairment with advanced age; the attitude of the person’s General Practitioner; acceptance of age-related decline coupled with increasing unwillingness to
interfere with the natural ageing process; and a belief that older people benefit less from the vaccination.

Conversely, van Essen et al. (1997) found that people over 75 years old were less likely to be vaccinated but this proved not to be statistically significant, whilst Honkanen et al. (1996) could relate neither age nor gender to increased uptake.

Place of domicile
O’Reilly et al. (2002) also found that living in a deprived area increased uptake, as did Andrew et al. (2004), although findings were not statistically significant. However, Nowalk et al. (2004) found those living in suburban areas were more likely to be vaccinated than those living in inner city areas. Neither author offers any explanation for this but, as will be discussed later, one’s own perception of increased risk can influence acceptance of vaccination: perhaps the people living in deprived areas in Northern Ireland perceive their risk to be high. Higher income levels were cited in Norwalk et al. (2004) as being positive predictors of vaccination, which might be linked with living in the more affluent suburban areas.

One surprising finding in two U.K. studies (Gosney 2000, O’Reilly et al. 2004) given the current recommendations (DoH 2003), was that residence in a nursing or residential home or continuing care facility was not predictive of being vaccinated, although no suggestions are made to explain this. O’Reilly et al. (2002) made no distinction between those who lived in nursing or residential homes, and those who did not, analysis was by postcode, assuming that anyone over 65 with the same postcode as a residential or nursing home was living there. There is acknowledgement of this tenuous assumption, but the finding that vaccination rates in these postcode areas were lower than average, means that it cannot be ignored and a suggestion is made for further, specific research. Gosney (2000) on the other hand, in a quantitative study of 279 people over 75 who had been admitted to hospital with acute medical problems, specifically inquired about place of residence and still concluded that it was not predictive of vaccination. However, self-report, coupled with a failure to
validate information given throws some doubt on these findings. The exclusion of patients on the basis of a mental test score may have improved the reliability of the information that was given but also excluded a group of very vulnerable patients, likely to be resident in nursing or residential homes, from the study. However, this was made explicit, along with the difficulty that would have been encountered in eliciting the reasons behind the vaccination decision.

Other risk factors
All of the authors who commented on the presence of identified risk factors or co-morbidity, advanced age, diabetes, chronic heart, respiratory or renal disease, agreed that this increased the likelihood of being vaccinated (Honkanen et al. 1996, Gosney 2000, O’Reilly et al. 2002, Kamal et al. 2003, Andrew et al. 2004). Kamal et al. (2003) in particular, found that vaccination rates increased parallel with the number of risk factors present and that people without identified risk factors were less likely to be vaccinated. Gosney (2000) identified that many of her subjects had one or more of the risk factors mentioned above in addition to age and comments that although this increased the likelihood, it did not ensure vaccination.

Marital status
Being married or living with a partner or spouse was strongly predictive of vaccination acceptance (Kamal et al. 2003, Norwalk et al. 2004, Andrew et al. 2004) but there is no discussion of the reasons for this. O’Reilly et al. (2002, p.388) refer to the ‘healthy survivor effect’ as being a reason for reduced vaccination rates. This effect infers that having been widowed reduces the desire to protect one’s health. However it is also possible to assume that the opposite might also be true.

Lifestyle
Higher educational achievement and income predicted higher vaccination uptake (Kamal et al. 2003, Andrew et al. 2004, Nowalk et al. 2004). This might be attributed to better understanding of health promotion messages, leading to increased health awareness and the adoption of
more health protective behaviours. Andrew et al. (2004) found those who took regular exercise to be more likely to be vaccinated, on the other hand a relationship between smoking and/or regular alcohol consumption and increased uptake was also established. Although alcohol consumption did not survive statistical analysis as a predictive factor, it was suggested that smokers perceived their risk to be higher and were therefore, vaccinated (Andrew et al. 2004). In addition, Nowalk et al. (2004) and Kamal et al. (2003) found caucasians as opposed to non-caucasians, more likely to accept vaccination.

**Prior experience**

Prior experience - personal or that of others - can have a positive or negative influence on the decision to accept or reject vaccination. Telford and Rogers’ (2003) qualitative study of 20 people 75 or over, purposively selected to include 10 people who had accepted vaccination and 10 who had refused, used semi-structured in-depth interviews to identify 3 main themes of which prior experience was one. They found that experience of having lived through an influenza epidemic or having listened to the stories of someone who has might also be influential. Whether it influences a person to accept or refuse vaccination depends on what was experienced. For instance, having been severely ill or knowing someone who has been severely ill, hospitalised or even died because of influenza, is likely to influence positively. Similarly, being vaccinated or listening to someone who has been vaccinated and not experiencing illness due to influenza, is likely to influence for the vaccination (Telford & Rogers 2003). But these were not the only prior experiences appearing to have influence. Personal biography and the biographies of those around them, norms, values and beliefs about healthy living, preserving health and preventing illness, established and internalised over the course of a lifetime, were a strong influence in the decision making process (Cornford & Morgan 1999, Telford & Rogers 2003).

Conversely, lack of experience or contact with others who have experienced the negative effects of influenza, might influence against the vaccine. Experience of side effects, personal or anecdotal, has in some
studies been associated with subsequent refusal of vaccination (Honkanen et al. 1996, van Essen et al. 1997, Gosney 2000) but this had been shown to depend on the attitude of the individual. Cornford and Morgan (1999) conducted qualitative, semi-structured interviews with 25 vaccinated and 25 unvaccinated people aged 75 or over, selected on the basis that they were at risk from influenza. Interpretation of side effects, personal or in others, was found to be more important than the experience itself. Both Telford and Rogers (2003) and Cornford and Morgan (1999) highlight that the older person is more likely to continue to accept vaccination when they are aware that the vaccine is different each year. The older people in these studies held the belief that side effects might be experienced some years and not others, depending on the constituents of the vaccine that particular year, but on the whole they believed that the benefits of the vaccine outweighed the risks.

Modern injection equipment and techniques can make the whole experience much more comfortable. However, it might be argued that an older person whose last experience of being vaccinated was perhaps 40 or 50 years ago might expect the same experience now and be reluctant to undergo the procedure again.

**Concerns about the vaccine**

The literature identifies a range of concerns that: the vaccine may not be effective; the vaccine can cause influenza or other illness; the vaccine may have possible side effects; and the vaccine is not safe.

The NHS Centre for Reviews and Dissemination (1996) categorically states that modern influenza vaccines are safe, effective, cannot cause influenza and are relatively free from serious side effects. Efficacy has been estimated to be between 60 and 90% with reductions in morbidity and mortality estimated at between 50 and 69% (NHS Centre for Reviews and Dissemination 1996, Potter 2001, Liddle & Jennings 2001). Randomised controlled trials have established that the frequency of systemic side effects in placebo groups and vaccinated groups are equal and local side

The issue, then, does not concern the safety of the influenza vaccine, its effectiveness or potential side effects but rather the attribution of any adverse event occurring after vaccination, to the vaccine. In other words, what people believe about the vaccine. A belief that the vaccine is safe, effective, cannot cause influenza and that any adverse effects that might be experienced are coincidental or preferable to influenza itself, is associated with vaccine acceptance. Conversely, the belief that the vaccine is not safe, not effective, causes influenza or side effects is associated with non-vaccination (Honkanen et al. 1996, van Essen et al. 1997, Cornford & Morgan 1999, Gosney 2000, Liddle & Jennings 2001, Telford & Rogers 2003, Nowalk et al. 2004). For example, Gosney (2000) found that only 30% of unvaccinated people thought the vaccine was effective compared to 95% of vaccinated people. Whilst 42% of unvaccinated people expressed concern about side effects, only 14% of vaccinated people expressed these concerns. It would seem therefore, that personal beliefs and experiences are important in the decision-making processes of older people.

**Perceived risk**

The risks identified by older people in the literature are divided into the risks associated with influenza per se, personal risks and consequences of contracting influenza and the risks associated with having the vaccination.

Honkanen et al. (1996) in a quantitative survey of 409 people over the age of 65 living outside institutions, established a link between older people’s perceptions of the seriousness of influenza and acceptance of vaccination. When asked if influenza was serious and had they been vaccinated, 15% felt it was a mild disease and 33% of these had accepted vaccination. A further 66% thought it was quite serious and 52% of these people had been vaccinated. Nineteen percent thought influenza to be serious of which 70% had been vaccinated.
This study was conducted in Finland and although subject to the limitations of self-reporting, this was later found to be 93.4% concurrent with health records. Vaccination was offered free of charge, although it is not stated whether this is usual in Finland. The study also considered most of the co-morbidities identified by the Department of Health as increasing the risks from influenza (DoH 2003) and the findings – that the existence of co-morbidity increases the likelihood of vaccination - concur with other studies (for example Gosney 2000, O’Reilly et al. 2002, Kamal et al. 2003, Andrew et al. 2004).

An association between the perception that influenza is not dangerous and reduced vaccination rates was also found by van Essen et al. (1997) in a quantitative study in the Netherlands of 243 people aged over 65 (with no other risk factors) invited by their G.P. to attend vaccination. The study was conducted approximately six months after the invitations were sent in an epidemic year. Findings therefore may have been influenced by these factors but the correlation is supported by the fact that individuals had accepted (or refused) vaccination for several consecutive years.

Cornford and Morgan (1999) investigated older people’s perceptions of the seriousness of influenza, in a qualitative study of purposively selected subjects who all had risk factors. A few people felt that it was never serious or that it was inconvenient rather than serious and was therefore a minor ailment. Most (80%) felt it might be serious for some people but did not see it as a threat to them personally. Only 10% thought influenza might be a risk to them. Although they were selected for inclusion in the study because they had at least one chronic illness recognised as putting them at increased risk of complications or death attributable to influenza, 94% of these people perceived themselves to be ‘healthy’ and so by inference, presumably not at risk. This would support the assertion that an older person’s subjective assessment of their own health, often arrived at by comparison with others less able, may not be congruent with other ‘objective’ assessment.
Many authors have identified the association between the individual’s perception of their own health status and acceptance of the vaccine. If the individual felt their health to be good, perceived or actual, they were less likely to be vaccinated. People who consider themselves to be healthy are less likely to consider themselves susceptible to influenza (van Essen 1997) and more likely to underestimate the risks and complications associated (Liddle & Jennings 2001). Their perception that they are not at risk renders the vaccine unnecessary (Gosney 2000, Telford & Rogers 2003) therefore, appealing to ‘at risk’ status may not be a useful strategy (Cornford & Morgan 1999). This perception, however, is subject to re-evaluation in light of new experiences, personal or of others, possibly leading to an increased willingness to accept vaccination.

People who perceive their health to be poor are more likely to be vaccinated (Honkanen et al. 1996, van Essen et al. 1997, Liddle & Jennings 2001, Kamal et al. 2003, Andrew et al. 2004). Perceptions of poor health might lead to an increased recognition of the risk from influenza itself or from a complication of any existing medical condition, and therefore lead people to seek vaccination. A simpler explanation might be that ill people have more contact with health care professionals who might have advised vaccination and provided more opportunity to be vaccinated. For example, Kamal et al. (2003) found that consulting with a doctor within the previous year was associated with higher vaccine uptake.

**Advice and information**

to avail themselves of the protection offered by influenza vaccination, older people first require the knowledge that it is available and second, how to get it. The main sources of information about the influenza vaccination for older people are radio, newspapers and relatives or friends (Honkanen et al. 1996). Reasons commonly cited for failure to be vaccinated include ignorance of a campaign, lack of information, misunderstanding information, lack of a direct offer and lack of personal recommendation or invitation (Gosney 2000, Liddle & Jennings 2001, Nowalk et al. 2004). Gosney (2000), in a study of older people admitted
to hospital with acute illness, found that 39% of them were either
unaware of the existence of the vaccine or did not know how to obtain it.
There was also a mistaken belief among some respondents that the
vaccination campaign was aimed at babies and children and not older
people.

It is well documented that information and a recommendation to be
vaccinated from a health care professional increases the likelihood of
acceptance (Gosney 2000, Liddle & Jennings 2001, O’Reilly et al. 2002,
Nowalk et al. 2004). O’Reilly et al. (2002) cite it as the most common
reason for presenting for vaccination. The amount, nature and type of
information and even the person giving it, can all influence the decision to
accept or refuse vaccination. Honkanen et al. (1996) found that
information given by health visitors was most successful in raising
vaccination rates even amongst those who were unfavourably disposed
towards vaccination. However, the role of the Finnish health visitor is not
defined and this finding may not therefore, be transferable to the U.K.
setting as the role of our health visitors might be different.

Gosney (2000) also found that information given by a nurse was more
likely to result in vaccination than if the information was given by a G.P.
Nowalk et al. (2004) describe how older people are more likely to be
vaccinated if they believe that their doctor, family or friends thought they
should, and that only half of the unvaccinated believed their doctor had
recommended it. The recommendation of health care professionals and
family would therefore, appear to be important. However, Telford and
Rogers (2003) dispute this, asserting that lay beliefs and perceived
personal risk assume more importance than professional recommendation
and government advice, whose approach to promoting influenza
vaccination is seen as ‘dictatorial and irrelevant’ by older people (Telford &
Rogers 2003, p.752).

RECOMMENDATIONS FOR PRACTICE
Clear, concise information about the risks of influenza, who is at risk and
the risks and benefits associated with being vaccinated is needed both for
All health care professionals need to be aware of their role in promoting the vaccine and using every opportunity to identify, educate, advise, remind and vaccinate eligible people. Computer systems in G.P. practices, outpatient departments and day care facilities might help to identify appropriate people, highlighting them on clinic lists. Personal written invitations, posters in local shops, reminder notes on prescriptions and opportunistic vaccination (Gosney 2000, Liddle & Jennings 2001) are approaches that can be used. Other approaches might even include pharmacists who have regular contact with patients using their dispensing software to flag up patients at risk, as identified by their prescription drugs, giving opportunity to educate, remind and recommend vaccination (Honkanen et al. 1996, Gosney 2000, O’Reilly et al. 2002, Kamal et al. 2003). Easy access to vaccination via drop-in clinics and visits by practice or community nurses to day-care centres, residential homes, sheltered housing complexes and the housebound, may improve uptake rates (Nowalk et al. 2004, Liddle & Jennings 2001).

The most effective method of improving uptake might be to enhance recognition of personal susceptibility and promote the vaccine as a health maintenance issue, placing it within the strongly held health beliefs of older people (Telford & Rogers 2003).

RECOMMENDATIONS FOR RESEARCH
During the course of this review, a number of methodological weaknesses have been identified in the published research. These include:

- Inaccuracies in comparing ages between the sexes
- Lack of representation amongst different types of General Practices
- Reliance on old data
- Predominance of self-report data
- Lack of discrimination between place of abode
• Exclusion of some patients due to application of mental test scores
  Studies completed in other countries not necessarily transferable.

Future research is therefore required which takes into account all the above limitations.

CONCLUSION
There is a wealth of demographic information, which is interesting and illuminating in identifying those likely or unlikely to accept vaccination, and will be useful when deciding, at a strategic level, where future efforts to improve uptake might be targeted. However, there is a mis-match between the lay and professional concepts and perceptions of influenza, its’ possible consequences, the vaccine and indeed health itself. At an individual consultation level, information about the older person, their health beliefs, values and attitudes will be more useful, allowing adoption of a person-centred approach to health promotion in general and promoting influenza vaccination in particular. Research designed to investigate these concepts and perceptions might promote congruence between lay and professional beliefs: this type of information is scarce but without it our efforts are unlikely to be successful.

</table>

Previous years vaccination status, level of knowledge about the campaign and source of information, co-morbidity, Previous experiences and beliefs regarding influenza vaccination and beliefs about influenza itself

Statistical analysis using SSP for Windows t-test to determine significance of difference between means

Influenza vaccination offered free of charge ? usual situation in Finland

Those born in even years also offered pneumococcal vaccine

Predictive factors for acceptance included a perceived need for the vaccine, belief in it’s adverse effects

Belief in adverse effects was negatively associated with vaccine acceptance

Health care professionals need to recognize the importance of their role in promoting the vaccine

<td>O’Reilly et al 2002 U.K.</td>
<td>To explore the variations in vaccination rates with special reference to uptake amongst older people</td>
<td>All those at risk of influenza and its complications registered with 12 practices in Northern Ireland Purposive</td>
<td>Data extracted from existing computerised medical records</td>
<td>Data relating to age, sex, co-morbidity and vaccination status</td>
<td>Differences between categorical variables tested using Chi-square test</td>
<td>Not discussed</td>
<td>Uptake rates peaked at age 85 and declined thereafter</td>
</tr>
</tbody>
</table>

Presence of co-morbidity increases the likelihood of vaccination even in older patients.

Living in a nursing or residential home decreases likelihood of vaccination.
