Abstract

One of the major drawbacks to using speech as the input to any pervasive environment is the requirement to balance accuracy with the high processing overheads involved. This paper presents an Arabic speech recognition system (called UbiqRec), which addresses this issue by providing a natural and intuitive way of communicating within ubiquitous environments, while balancing processing time, memory and recognition accuracy. A hybrid approach has been used which incorporates spectrographic information, singular value decomposition, concurrent self-organizing maps (CSOM) and pitch contours for Arabic phoneme recognition. The approach employs separate self-organizing maps (SOM) for each Arabic phoneme joined in parallel to form a CSOM. The performance results confirm that with suitable pre-processing of data, including extraction of distinct power spectral densities (PSD) and singular value decomposition, the training time for CSOM was reduced by 89%. The empirical results also proved that overall recognition accuracy did not fall below 91%.

1. Introduction

Speech is the primary and most convenient means of communication between humans [1]. Current human computer interfaces (HCI), like keyboards or mouse are inadequate for ubiquitous/wearable environments. For such environments, speech based inputs are gaining interest because it permits both the hands and eyes to be kept free and therefore less restricted in its use and can achieve quicker communications [2].

The motivation behind this work is to develop a pervasive bioinformatics environment where a speech engine is used as the human-machine interface. For this particular study, Arabic language data [3] has been used to test the efficiency of the speech recognition engine. To develop a continuous Arabic speech recognition system, the input speech is segmented into phonemes using suitable segmentation techniques [4] such as Blind Speech Segmentation [5], Energy Based End Point Detection [6], Zero Crossing Rate and techniques based on Phonetic and Acoustic cues [7, 8]. The novel phoneme-based recognition engine that is presented in this paper is then used for classification. This paper will focus particularly on the classification of Arabic phonemes [9], which is an especially challenging task due to the highly glottal and contextual dependency of the language.

In the proposed classification system Self Organizing Maps (SOM) are used as classifiers. SOM are characterized by a vector space comprising different patterns that exist in the input data space. These vector spaces are developed based on the excitatory and inhibitory behavior of the output neurons in SOM [10]. A single neuron or a group of neurons in the output layer contributes to a distinct input in time and space that results in classification and statistical data extraction. This feature has been exploited in this paper to facilitate accurate Arabic phoneme identification.

SOM have a wide range of applicability to complex real world problems ranging from speech recognition to optical character recognition [11]. Kohonen [12] discussed visualization of machine states such as transformers through the application of SOM. Kohonen also identified several important application domains: such as texture analysis and classification, robotics, telecommunication, designing, measuring and testing methods for SOM.

Several studies have shown that CSOM perform better than simple SOM due to their weight optimization for a specific class. Neagoe and Ropot
2. Hybrid Speech Recognition System

To recognize the consonants, the PSD [20] of the input speech signals are computed with maximum frequency of 8 kHz. In general, consonants are very difficult to identify in the time-domain because of the variation in noise levels and speaker dependent properties in the speech signal. In order to extract the dominant frequencies using PSD, several time windowing approaches were evaluated including Hanning, Hamming, Bartlet, Welch and Gaussian [21]. Hamming and Hanning windows perform better for tonal languages like Mandarin and English, but for Arabic phonemes, performance is superior for the Gaussian window, due to the fact that Arabic is a glottal language and has fewer high frequency components compared with tonal languages.

To obtain the PSD using a Gaussian window, the sampled speech signal $S$ is split into overlapping segments (windows) each with the Gaussian window vector. The coefficients of the Gaussian window are
calculated using equation (1). The length of the window is \( N \), \( k \) is the sample index and \( G \) is the output signal.

\[
G(k + 1) = e^x
\]

(1)

Where \( x = \frac{1}{2} \left[ \log \left( \frac{k + \sqrt{k^2 + N^2}}{2} \right) \right]^2 \), \( 0 \leq k \leq N \) and \( \alpha \leq 2 \).

A frequency resolution of 20Hz is used for the PSD with zero-padding, so it is an accurate estimate of the short-term, time-localized frequency content of \( S \). In the PSD the time increases from left to right and frequency from bottom to up (ranging from dc to 8 kHz). The average length of \( S \) is 61,000 samples and the PSD is a complex matrix with average size of 4000 x 16.

The singular values \( SV \) are calculated from the PSD matrix, which is \( m \times n \) matrix and decomposed into three matrices given by:

\[
X = UST^*
\]

(2)

such that \( UU^T = VV^T = I \). Here \( U \) and \( V \) are two unitary matrices and \( S \) is a diagonal matrix containing singular values of \( X \) in descending order. Since every matrix has a unique set of singular values therefore this uniqueness is exploited in developing different recognition systems. The advantage is the reduction in computational time and memory requirements as demonstrated later in the paper.

Concurrent Self Organizing-Maps (CSOM) was trained on the first ten \( SV \) values. SOM algorithm [10] is based on the principle of winner takes all, which keeps certain biological similarity with the cortical maps. The input vector for SOM is \( SV \) (first 10 singular values), and weights between the input layer and the maps are \( w \), the winning neuron \( k \) is:

\[
k = \min_i \| SV - w_i \|
\]

(3)

This particular neuron excites the neurons in its neighbourhood according to the Mexican hat function given by:

\[
C(k_i, k_j, t) = \exp \left( \frac{\| k_i \| - \| k_j \|}{\alpha(t)S} \right)
\]

(4)

where \( S \) is the number of neurons per dimension, \( k_i \) is the winner neuron, \( k_j \) is the neighbour of winning neuron and \( \alpha(t) \) is the learning rate.

Hebb’s learning algorithm for SOM is now applied. This postulates that a synaptic connection is more efficient when the pre-synaptic firing and the post-synaptic firing occur simultaneously as shown in (5) and (6).

For the winner neuron domain

\[
\frac{\partial w_{k}}{\partial t} = \alpha(t)(SV - w_{k})
\]

(5)

For other neurons

\[
\frac{\partial w_{k}}{\partial t} = 0
\]

(6)

Some researchers have categorically stated that using pitch [22] as a recognition parameter is not a good choice, due to its speaker dependency in developing Speaker Independent Speech Recognition (SISR) systems [23]. Significant research however has also shown that pitch can be used to increase the accuracy of recognition systems. Kitaoka et al [24] worked on glottal sound source features and concluded that glottal features like pitch can be used for SISR systems. Wong and Chang [25] worked on the effects of pitch and lexical tone on different Mandarin speech recognition tasks and found that by considering the tone contexts and incorporating pitch feature lead to higher recognition accuracy. Similarly Chen and Chang [26] developed a recognition system based on Dynamic HMM (DHMM) using pitch values. The results showed that the DHMM achieves approximately a 10% relative error reduction both in base-syllable and tonal syllable recognition tasks. The research presented in this paper also supports this fact and uses pitch as a post-processing layer within the hybrid structure proposed for recognition. The results discussed in Section 3 and 4 show a significant increase of 19% in the overall recognition accuracy.

3. Implementation of Speech Recognition Algorithm

The mathematical model detailed in Section 2 was simulated using MATLAB 6.5.1. The complete phoneme recognition algorithm is defined in Figure1. The input phoneme is processed and the PSD calculated in steps 1 and 2. The singular values are then extracted from the PSD (step 3) and used by the CSOM architecture. The recognition system iteratively computes the Euclidean distance \( E \) between the input vector and all SOMs present in CSOM. If the distance is less than the empirical threshold \( \varepsilon \), then this particular phoneme \( i \) is a candidate phoneme, and all such candidate phonemes are added to vector \( PID \) (steps 4 to 9). If no candidate phoneme is identified then the system is unable to recognize the sound, otherwise the phoneme is identified based on the similarity of the standard SOM response and the response of the input signal. If a unique identification of the input sound wave is not obtained, then the
conflict is resolved by activating a pitch analyzer, shown in steps 13 through 16.

The recognition system was trained for 28 basic Arabic phonemes [9] on 100 sound samples for each phoneme. The input sound data was obtained from [20], with 70% of the recorded sounds used for training the SOM. Two layered pre-processing was performed before the training of SOM. In the first layer, PSD values were calculated to facilitate the recognition of consonants from the input speech. As mentioned in Section 2, for spectrogram calculations, the maximum frequency = 8 kHz, frequency resolution = 20 Hz and a Gaussian windowing function was used in (1). The second pre-processing layer implements the SVD to capture the prominent features of respective PSD values (Step 3 in Figure 1). The SVD analysis shows that the first 10 singular values effectively represent the PSD, so \( m = 10 \) in Step 3 of Figure 1. Several SOM were developed for each phoneme in the development phase and were tested for accuracy against different phonetic sounds. The final SOM for each phoneme was selected based on the individual performance in terms of percentage recognition accuracy.

4. Experimental Results

Once the individual SOM were optimized for highest possible classification rate, all SOM were integrated to form a concurrent architecture. This arrangement of CSOM was extensively tested for validation of the data set. It was noted that certain phonemes were misclassified, resulting in an overall decrease of recognition accuracy from 91.7% to only 71.9%. The results for CSOM are shown in A2 in Table 1. The recognition accuracy of /a:/ which was previously recorded as 100% (A1 in Table 1) dropped to only 56.25% (A2 in Table 1). This reduction in accuracy was due to the misclassification of /a:/ as /H/ (CP in Table 1). Similar discrepancies were identified for the /b/, /H/ and /zh/ phonemes.
In order to solve this misclassification problem, a post processing layer was added, which compared the standard pitch contours with pitch contours of the input sounds. Experiments showed that distinct pitch contours were present for most of the misclassified phonemes when tested for all the speakers. For example, in the case of /a:/, there was no pitch in the initial 5 frames, whereas a continuous band of pitch was observed for /a:/ during the same time period. This is shown in Figures 2 and 3. Similarly /a:/ has continuous pitch in the initial frames while /H/ has no pitch in this region. Phonemes /i/ has continuous pitch in the initial frames opposed to /H/. Therefore, any misclassification between /a:/ - /H/, /a:/ - /x/ and /i/ - /H/ can be resolved using the pitch information. Similar analysis was conducted for all the phonemes and their misclassifications. A pitch analyzer compared the standard pitch contours and the pitch contours of the input sound was added as a post-processing layer in the hybrid system, resulting in an overall recognition accuracy up to 90.8% as shown in A3 of Table 1.

The training and recognition times of the SVD-based recognition system were recorded and compared with the non-SVD based recognition system i.e., the SOM were directly trained on the PSD. The experiments confirmed an improvement in the CPU throughput from 80.35% to 89.48% in both training and recognition.

5. Conclusions

This paper presents a hybrid Arabic phoneme recognition system for pervasive environments, based on PSD, singular values, self-organizing maps and pitch contours. The study indicates that training and recognition time of CSOM has been dramatically reduced due to the introduction of SVD. With the introduction of pitch contours as a post processor, recognition accuracy increased from 71% to above 90%, confirming the judgment to use the pitch features in phoneme recognition for various phonetic sounds. An overall recognition accuracy of 90.84% was observed with reduction in training and recognition time by a factor of 80.38% and 89.48% respectively. This recognition accuracy compares very favorably with the performance of other systems such as those identified in [3, 13, 14, 15, 17].
