The Herschel view of GAS in Protoplanetary Systems (GASPS)

First comparisons with a large grid of models*

ABSTRACT

The Herschel GASPS key program is a survey of the gas phase of protoplanetary discs, targeting 240 objects which cover a large range of ages, spectral types, and disc properties. To interpret this large quantity of data and initiate self-consistent analyses of the gas and dust properties of protoplanetary discs, we have combined the capabilities of the radiative transfer code MCFOST with the gas thermal balance and chemistry code ProDiMo to compute a grid of ≈300,000 disc models (DENT). We present a comparison of the first Herschel/GASPS line and continuum data with the predictions from the DENT grid of models. Our objective is to test some of the main trends already identified in the DENT grid, as well as to define better empirical diagnostics to estimate the total gas mass of protoplanetary discs. Photospheric UV radiation appears to be the dominant gas-heating mechanism for Herbig stars, whereas UV excess and/or X-rays emission dominates for T Tauri stars. The DENT grid reveals the complexity in the analysis of far-IR lines and the difficulty to invert these observations into physical quantities. The combination of Herschel line observations with continuum data and/or with rotational lines in the (sub-)millimetre regime, in particular CO lines, is required for a detailed characterisation of the physical and chemical properties of circumstellar discs.

Key words. astrochemistry – circumstellar matter – protoplanetary disks – stars: formation – radiative transfer – line: formation

1. Introduction

The dust phase of circumstellar discs has received a lot of attention in the last few decades, giving us a clearer picture of their structure and dust content through many continuum surveys in various wavelengths regimes (e.g. Beckwith et al. 1990; Andrews & Williams 2007; Evans et al. 2007), complemented by detailed studies of individual objects, combining spectral energy distributions (SEDs) and resolved maps in scattered light and thermal emission (e.g. Pinte et al. 2008; Duchêne et al. 2010).

Although gas represents 99% of the initial mass of discs, it has been more difficult to observe and is mostly restricted to millimetre lines probing the cold outer disc, where the freeze-out of molecules is important (e.g. Dent et al. 2005; Schaefer et al. 2009), and near-IR lines which are only emitted from the hot inner parts of discs (e.g. Najita et al. 2003; Brittain et al. 2007). The high sensitivity of Herschel (Pilbratt et al. 2010) opens an opportunity to systematically probe the gas phase of discs, in particular the warm atomic and molecular layer responsible for the bright gas emission lines in the far-IR. The GASPS open time key program (see Dent et al., in prep.; and Mathews et al 2010) is a large survey of gas in discs with a gas mass sensitivity comparable to the dust surveys. GASPS will observe several atomic and molecular lines in about 240 protoplanetary disc systems with ages in the critical 1 to 30 million year age range during which planets form and the gas seems to dissipate.

The interpretation of gas observations is complicated by the large number of processes at play: processing of radiation by dust grains, disc thermal structure, chemistry, excitation and destruction of molecules, freeze-out and desorption on the dust grains, etc. To estimate the relative importance of these mechanisms as a function of age, stellar properties, disc structure, and dust content, we have computed a large grid of synthetic SEDs and gas emission lines, named Disc Evolution with Neat Theory (DENT, Woitke et al. 2010). Here, we confront the trends identified in the DENT grid with the first GASPS observations.

2. The DENT grid and initial GASPS data

The DENT grid is intended as a statistical tool to investigate the influence of stellar, disc, and dust properties on the various continuum and line observables, and to study to what extent these dependencies can be inverted to retrieve disc properties. The grid
3. Results and discussion

One of the main reasons to compute the DENT grid was to estimate the degeneracies between parameters, i.e. how they influence the various lines and how far \textit{Herschel} line observations can be inverted to assess the physical and chemical conditions of the disc. Not surprisingly, the DENT grid revealed that many parameters affect the predicted line fluxes and SEDs, and degeneracies between parameters are common and complex, which makes the interpretation of lines fluxes difficult.

3.1. Gas heating processes

Figure 1 plots the [OI] 63 $\mu$m line flux as a function of the stellar luminosity (left panel) and accretion luminosity (right panel). Red and blue points, stars, triangles, and diamonds represents GASPS observations. Points are T Tauri stars while stars are Herbig stars. Diamonds are sources with extended emission, which could originate from an outflow or envelope. Triangles are GASPS upper limits. Names are only indicated for SDP sources (blue). Black pluses are ISO observations. Observations were scaled to a distance of 140 pc. The crosses show the median values of the DENT models. The full vertical lines represent the 1-sigma range of models. Only models with a gas mass larger than $10^{-4} M_{\odot}$ are plotted. Green and purple points are high- and low-UV models respectively ($f_{\text{UV}} = 0.1$ and 0.001). Accretion luminosities from Hartmann et al. (1998) and Garcia Lopez et al. (2006).

relied on the combined capabilities of the 3D radiative transfer code MCFOST (Pinte et al. 2006, 2009) and the gas thermal balance and chemistry code ProDiMo (Woitke et al. 2009; Kamp et al. 2010). Spectral energy distributions and line fluxes of [OI], [CII], $^{12}$CO, ortho-H$_2$O and para-H$_2$O are predicted for more than 300 000 discs models. The DENT grid was built by systematically exploring an 11-dimension parameter space (see Woitke et al. 2010, Table 1). In particular the DENT grid explores the effect of varying the central star (age, mass, UV excess), disc dust mass and gas-to-dust mass ratio, inner and outer radii, flaring and surface density exponents, grain sizes, and presence of dust settling. It is important to keep in mind that even with the large number of calculated models, the sampling of each parameter remains coarse and that the DENT grid does not reflect the statistics of objects in GASPS (each parameter has been sampled uniformly and not following the distributions of the GASPS target list). We refer the reader to Woitke et al. (2010) for details about the grid properties and computational implementation.

We include here data obtained during the science demonstration phase (SDP, Mathews et al. 2010), as well as GASPS data reduced prior to 2010 April 23, which will be presented in detail in following papers. Due to the limited number of sources, statistical analyses remain premature, but initial comparisons with the model predictions are necessary to ensure that the range of models cover the GASPS observations.

X-ray irradiation, which is not yet included in the DENT grid, can also contribute significantly to the gas heating and chemistry for low-mass objects (e.g. Glassgold et al. 2004; Semenov et al. 2004; Meijerink et al. 2008; Hollenbach & Gorti 2009; Ercolano & Owen 2010) and higher fluxes can be expected for sources with typical T Tauri X-ray emission. The small number of sources observed by GASPS so far prevents us from distinguishing between UV and X-rays for the main heating process for low mass objects. The full GASPS survey should provide detailed answers on these aspects.

Figure 2 presents the [OI] 145 $\mu$m and [CII] 158 $\mu$m line fluxes as a function of the [OI] 63 $\mu$m line. The models are in excellent agreement with the GASPS observations. The DENT grid predicts a correlation between the [OI] 63 and 145 $\mu$m line fluxes. A regression fit of all the DENT points indicates that both line fluxes are almost proportional ($f_{\text{[(OI] 145 $\mu$m)}} \propto f_{\text{[OI] 63 $\mu$m)}}^{0.08}$), with a [OI] 145/63 line ratio around 0.05 on average. The presence of scatter in the plot illustrates the wide range of physical conditions encountered in the DENT grid. The correlation, however, is very strong (Pearson correlation
These results agree with the prediction of Tielens & Hollenbach (1985) for a 1D photodissociation region (see their [OI] lines, and it is very sensitive to the amount of UV radiation.\)

\[\text{In the left panel the line corresponds to the average ratio in the DENT grid: 0.05. This ratio corresponds to the limit case for optically thick lines at temperatures higher than a few hundred Kelvin (Tielens & Hollenbach 1985).}\]

\[\text{The right panel of Fig. 3 shows the correlation between the}\]

\[\text{Gas mass and gas-to-dust mass ratio}\]

In addition to the main trend of an increasing line flux with (UV) luminosity, there is also a trend with gas mass, where the synthetic line flux increases with mass, but the correlation seems to saturate above $10^{-23} M_\odot$ (see also Woitke et al. 2010), preventing direct inversion of the line flux into a gas mass (Fig. 3).

The right panel of Fig. 3 shows the correlation between the [OI] 63 μm line flux and the adjacent continuum. Because the line and continuum emissions are optically thick in most cases, these fluxes give an indication of the relative temperatures and projected surface area of the emitting regions (gas and dust). As the stellar luminosity increases, the region of the disc which is warm enough to contribute significantly to the emission also increases, resulting in larger fluxes. This behaviour is observed for most GASPS sources where the line flux roughly increases with the continuum level, but with a significant scatter. As a consequence, this indicates that a large fraction of discs with a significant far-IR excess will be detected in [OI] by Herschel. The separation of the DENT models according to their gas-to-dust mass ratio suggests that most objects are gas-rich (gas/dust mass ratio >10). The large scatter in the models, and the optical depth in the continuum and the line, precludes however, in most cases, a precise estimate of the gas-to-dust ratio for individual sources. For instance, no direct ratio (or upper limit for HD 181327) can be estimated from this diagnostic alone for HD 169142 and TW Hydra, for which the line fluxes can be reproduced by any ratio between 1 and 1000. In addition, the contribution of an outflow to the line flux may affect the estimation of the disc gas-to-dust ratio and needs to be accounted for.

Greater observational constraints and more detailed modelling is required to estimate the gas mass and gas-to-dust ratio. In particular, the combination of low rotational level transitions of CO with oxygen lines offers a valuable proxy to estimate the amount of gas in discs. Figure 4 plots the $^{12}$CO $J = 3 \rightarrow 2$ line flux as a function of the [OI] 63 μm line flux. We stress that the accuracy in the calculated CO abundances is limited by our approximate treatment of self-shielding (see Woitke et al. 2009), but this does not affect our conclusions. For low-mass discs, this diagram allows a clear distinction of the gas disc mass. As the mass increases, lines become optically thick and the corresponding fluxes saturate, preventing determination of the gas mass. Current CO surveys can only reach sources in this saturation regime (see for instance data from Dent et al. 2005 in Fig. 4), but this perspective is particularly interesting in the context of ALMA, which will offer high sensitivity for CO lines ($\approx 10^{-23}$ W m$^{-2}$). Similar diagrams combining $^{13}$CO (not included in DENT, but see Meeus et al 2010 and Thi et al. 2010), C$^{18}$O and [OI] 145 μm, which saturate at higher masses due to lower optical depths, will further help to overcome this degeneracy. As oxygen lines are sensitive to warm gas in the inner 10–30 AU (for T Tauri stars), they offer complementary views to the low-J CO lines which probe...
irradiation for Herbig stars. This is a highly relevant point to be

The GASPS survey will offer unique views of the gas and dust
regions outside of 20–40 AU, especially when resolved maps
of the CO emission are available.

4. Summary and conclusions

The GASPS survey will offer unique views of the gas and dust
phases of protoplanetary discs. In order to provide statistical
tools to help the interpretation of the survey results, we inter-
faced the MCFOST and ProDiMo codes and calculated a large
grid of models sampling the range of discs observed by GASPS.
This will allow us to determine some of the physical condi-
tions within discs. The initial results from the GASPS survey
tend to confirm the predictions of the DENT grid, illustrating
the main parameters affecting the line fluxes, namely the UV ex-
cess and/or X-ray emission for T Tauri stars and the UV stellar
irradiation for Herbig stars. This is a highly relevant point to be
considered in subsequent open time programs on discs.

The interpretation of line results remains difficult and their
inversion into physical parameters must be performed with caution, because the DENT grid highlights considerable
degeneracies between parameters and the complex interplay
between various physical processes. The [OI] 63 μm is crucial
for breaking some of the degeneracies. By combining this line
with continuum and/or (sub)mm rotational lines, we can possi-
bly distinguish various parameters. Meeus et al (2010) and Thi
et al. (2010) illustrate how far this inversion can be performed
when high quality data sets are paired with a wide range of observational
techniques are available.
