Introduction

Aerosols, both water ice and dust, play a key role in the Martian climate. However, our understanding of the interactions between these aerosols and different components of the surface (solar ice caps, frost) in the atmosphere (vapour, ice clouds) and the distribution and properties of dust is currently incomplete.

Water ice clouds have been observed at many locations in the Martian atmosphere, and they occur in many different forms, such as polar hood clouds, ice caps/ice caps and ground fogs. The largest spatial distribution of clouds belongs to the aphelion cloud belt, which appears during northern hemisphere spring and summer each year in a zonal band between around 10°S and 30°N\textsuperscript{[1, 2].}

In this paper, we demonstrate the potential impact of water ice clouds on a Mars Global Circulation Model (MGCMM), and test the sensitivity of the model to varying dust opacity. We use independent model experiments and assimilations of the Mars Pathfinder Emissivity Spectrometer (TES) retrievals and validate the model against Mars Climate Sounder (MCS) observations.

Effects of water ice clouds in MGCMM simulations

It is known that cirrus clouds in the Earth's atmosphere can scatter and absorb incoming solar radiation, and absorb and emit thermal infrared radiation, causing a warming of the atmosphere\textsuperscript{[3, 4].} Therefore, due to the presence of water ice clouds in the Martian atmosphere, it is necessary to take into account their radiative effects in MGCMMs.

The current LMD MGCMM\textsuperscript{[5]} run in the UK uses a spectral dynamical core, and includes a simplified water cycle in which there is atmospheric transport of water vapour and ice, a bulk cloud scheme, and interaction with the Martian regolith\textsuperscript{[6, 7].} However, in the model run in the UK, the water ice opacity is not yet coupled with the MGCMM radiation scheme, so absorption of visible/infrared radiation by the water ice clouds is not taken into account. This absorption of radiation has been identified as being potentially significant in the equatorial/middle atmosphere of Mars around aphelion, when the planet-occluding cloud belt forms\textsuperscript{[8].} As can be seen in Figure 1, it appears as though the downward infra-red radiation emitted by the aphelion cloud belt is introducing a warming of the atmosphere not accounted for in the model.

Sensitivity of the model to dust distribution

Due to the radiative effects of dust, its temporal and spatial distribution will have a large effect on other atmospheric properties. To test the sensitivity of the MGCMM to the distribution of dust, two simulations with different dust distributions have been run using the UK version of the LMD MGCMM.

The two dust schemes used in the independent simulations are derived from assimilations of TES dust total optical depth. They are based on earlier and revised retrievals, henceforth denoted as 2003 and 2005 dust schemes. As with the other two schemes, both simulations used identical initial conditions.

Figure 2 shows the difference in visible dust opacity averaged over Mars month 5 for both dust schemes. As can be seen, the 2005 dust schemes show increased opacity globally, particularly in the southern hemisphere poleward of around 40°S.

Figure 3 shows the effect of this increased dust opacity on the southern hemisphere mid-winter. The 2005 dust scheme results in increased middle atmosphere warming, particularly over the poles, and especially over the north pole. The increase in temperature is attributed to the radiative effects of clouds, unlike the current UK version of the model. Strong temperature inversions can be seen close to the ground in the model simulations, these are not apparent in the MCS or MCD profiles, as they are too close to the surface to be resolved by the instruments.

Above around 40 km, there is no data from the TES, and so the profiles are less accurate. Even so, it can be seen that the assimilation of volcanoes improves the output of the MGCMM. This is to be expected as the assimilation includes the radiative effects of clouds, unlike the current UK version of the model. Strong temperature inversions can be seen close to the ground in the model simulations, these are not apparent in the MCS or MCD profiles, as they are too close to the surface to be resolved by the instruments.

As has been seen, the distribution of dust in the MGCMM has a large impact on atmospheric temperature. It would also therefore be expected to influence the temporal and spatial distribution of clouds, though such simulations have not yet been carried out.

Project aims

The project will model the Martian water cycle, including radiatively active water ice clouds, to interpret new observations from MCS. We will be using the latest version of the LMD MGCMM, which includes the new LMD physics routines. A unique data assimilation system\textsuperscript{[10]} will be used to obtain a complete, dynamically self-consistent reconstruction of the extraterrestrial circulation for the complete period of the MGS mission\textsuperscript{[10].} A series of diagnostic studies will be made to characterise the climatology and synoptic meteorology of Mars over seasonal and interannual timescales, identifying detailed case studies of events such as the formation of volcanic weather systems. The assimilation results can be used to test the validity of the new cloud schemes introduced to the model, improving our understanding of the Martian water cycle.

Acknowledgements

The authors thank L. Montabone and D. Muhoff for their assistance with the model simulations.
