Introduction

Aerosols, both water ice and dust, play a key role in the Martian climate. However, our understanding of the interactions between these species, the surface (solid ice caps, frost) in the atmosphere (vapour, ice clouds), and the distribution and properties of dust is currently incomplete.

Water ice clouds have been observed at many locations in the Martian atmosphere, and they occur in many different forms, such as polar hood clouds, ice crystal clouds and ground frost. The largest spatial distribution of clouds belongs to the aphelion cloud belt, which appears during northern hemisphere spring and summer each year in a zonal band between around 10° S and 30° N [1, 2].

In this poster, we demonstrate the potential impact of water ice clouds on a Mars Global Circulation Model (MGCM), and test the sensitivity of the model to varying dust opacity. We use independent model experiments and assimilations of Thermal Emission Spectrometer (TES) retrievals and validate the model against Mars Climate Sounder (MCS) observations.

Effects of water ice clouds in MGCM simulations

It is known that cirrus clouds in the Earth’s atmosphere can scatter and absorb incoming solar radiation, and absorb and emit thermal infrared radiation, causing a warming of the atmosphere [3,4]. Therefore, due to the presence of water ice clouds in the Martian atmosphere, it is necessary to take into account their radiative effects in MGCMs.

The current LMD MGCM [5] run in the UK uses a spectral dynamical core, and includes a simplified water cycle in which there is atmospheric transport of water vapour and ice, a bulk cloud scheme, and interaction with the Martian regolith [6,7]. However, in the model run in the UK, the water ice opacity is not yet coupled with the MGCM radiation scheme, so absorption of visible/infrared radiation by the water ice clouds is not taken into account. This absorption of radiation has been identified as being potentially significant in the equatorial middle atmosphere of Mars around aphelion, when the planet-averaging cloud belt forms [8]. As can be seen in Figure 1, it appears as though the downward intra-red radiation emitted by the aphelion cloud belt is introducing a warming of the atmosphere not accounted for in the model.

Sensitivity of the model to dust distribution

Due to the radiative effects of dust, its temporal and spatial distribution will have a large effect on other atmospheric properties. To test the sensitivity of the MGCM to the distribution of dust, we have performed several prominent dust cases using the LMD MGCM.

The two dust schemes used in the independent simulations are derived from assimilations of TES total dust opacity. They are based on earlier and revised retrievals, henceforth donated as 2003 and 2005 dust schemes. As compared to the MCD, both dust schemes were used identical initial conditions.

Figure 1. (a) Seasonal evolution of zonally averaged equatorial temperature bias over the course of the MGS mapping mission; white and black dots show data assimilated dust distribution, 185°F isotherm and approximate height of cloud condensation. (b) Seasonal cycle of total dust opacity at 6.5 hPa [8].

Figure 2. Difference in dust opacity between simulations with different dust schemes. As can be seen, the 2005 dust scheme produces increased opacity globally, particularly in the southern hemisphere poleward of around 40° S.

Effects of water ice clouds on a Mars Global Circulation Model (MGCM), and test the sensitivity of the model to varying dust opacity. We use independent model experiments and assimilations of Thermal Emission Spectrometer (TES) retrievals and validate the model against Mars Climate Sounder (MCS) observations.

Figure 3. Difference in temperature between simulations run with different TES dust schemes (2005 – 2003), averaged over the northern hemisphere. The implementation of the 2005 dust scheme leads to increased middle atmosphere warming, particularly over the poles, and especially over the north pole. The increase in temperature can be attributed to the adiabatic warming of the air that is sinking over the poles. The increased dust in the atmosphere from the 2005 scheme leads to increased middle atmospheric circulation, and hence increased polar warming.

Figure 4. 3. Plots of the meridional mass streamfunction (MMS) averaged over an entire Martian year are shown in Figure 4. The MMS from both the simulations and the modelled data from the Mars Climate Database (MCD) shows the dominance of the northerly circulation, though the temperature bias at the south pole in the MCD is not as strong as that from the assimilation. None of the plots accurately portray the southerly circulation that is present in the assimilation. The temperature profiles from the 2003 and 2005 dust schemes do show stronger southerly circulation than that from the MCD, but it is still weaker than in the assimilation.

Figure 5. Mean vertical profiles of temperature at varying latitudes from: (a) MY24 simulation using 2003 dust scheme; (b) MY24 simulation using 2005 dust scheme; (c) MY25 assimilation using TES dust and thermal retrievals; (d) MY25 assimilation using TES dust and thermal retrievals; (e) MCS limb retrievals with mean local times 03:16 LST and 15:36 LST; (f) MY25 assimilation using TES dust and thermal retrievals.

Above around 40 km, there is no data from the TES, and so the profiles are from the MCD. Even so, it can be seen that the assimilation of volatiles improves the output of the MGCM. This would also be expected as the assimilation includes the radiative effects of clouds, unlike the current UK version of the model. Strong temperature inversions can be seen close to the ground in the model simulations, but these are not apparent in the MCD or MCS profiles, as they are too close to the surface to be resolved by the instruments.

Figure 6 compares the temperature profile near the south pole in more detail. As can be seen immediately, the profiles from the simulation with the new dust scheme and the assimilation are in much closer agreement with the MCS observations than the profile from the MCD. The lower temperature close to the pole in the simulation are apparent, but the middle atmosphere warming agrees well with the MCS plot.

As has been seen, the distribution of dust in the MGCM has a large impact on atmospheric temperature. I would also therefore be expected to influence the temporal and spatial distribution of clouds, though such simulations have not yet been carried out.

Project aims

The project will model the Martian water cycle, including radiatively active water ice clouds, to interpret new observations from MCS. We will be using the latest version of the LMD MGCM, which includes the new LMD physics routines. A unique data assimilation system [10] will be used to obtain a complete, dynamically self-consistent reconstruction of the extra-galactic forcing for the complete period of the MCS mission to date. A series of diagnostic studies will be made to characterise the climatological and synoptic meteorology of Mars over seasonal and interannual time-scales, including detailed case studies of events such as the formation of cyclonic weather systems. The assimilation results can be used to test the validity of the new cloud schemes introduced to the model, improving our understanding of the Martian water cycle.
