Introduction

Aerosols, both water ice and dust, play a key role in the Martian climate. However, our understanding of the interactions between the ice cloud radiative properties and the surface (solar ice caps, frost) in the atmosphere (vapour, ice clouds) and the distribution and properties of dust is currently incomplete.

Water ice clouds have been observed at many locations in the Martian atmosphere, and they occur in many different guises, such as polar hood clouds, orographic clouds and ground fogs. The largest spatial distribution of clouds belongs to the aphelion cloud belt, which appears during northern hemisphere spring and summer each year in a zonal band between around 10° S and 30° N [1, 2].

In this paper, we demonstrate the potential impact of water ice clouds on Mars Global Circulation Model (MGCMI) and test the sensitivity of the model to varying dust opacity. We use independent model experiments and assimilations of Thermal Emission Spectrometer (TES) retrievals and validate the model against Mars Climate Sounder (MCS) observations.

Effects of water ice clouds in MGCMI simulations

It is known that cirrus clouds in the Earth’s atmosphere can scatter and absorb incoming solar radiation, and absorb and emit thermal infrared radiation, causing a warming of the atmosphere [3,4]. Therefore, due to the presence of water ice clouds in the Martian atmosphere, it is necessary to take into account their radiative effects in MGCMI.

The current LMD MGCM [5] run in the UK uses a spectral dynamical core, and includes a simplified water cycle in which there is atmospheric transport of water vapour and ice, a bulk cloud scheme, and interaction with the Martian regolith [6,7]. However, in the model run in the UK, the water ice opacity is not yet coupled with the MGCM radiation scheme, so absorption of visible/infrared radiation by the water ice clouds is not taken into account. This absorption of radiation has been identified as being potentially significant in the equatorial middle atmosphere of Mars around aphelion, when the planet-circling cloud belt forms [8]. As can be seen in Figure 1, it appears as though the downward infra-red radiation emitted by the aphelion cloud belt is introducing a warming of the atmosphere not accounted for in the model.

Sensitivity of the model to dust distribution

Due to the radiative effects of dust, its temporal and spatial distribution will have a large effect on other atmospheric properties. To test the sensitivity of the MGCM to the dust distribution, the two sets of experiments to be discussed in this paper have been run using the UK version of the LMD MGCM.

The two dust schemes used in the independent simulations are derived from assimilations of TES total dust opacity. They are based on earlier and revised retrievals, henceforth denoted as 2003 and 2005 dust schemes. As shown in the two dust schemes, both simulations used identical initial conditions.

Figure 2 shows the difference in visible dust opacity averaged over Mars month 5 for both dust schemes. As can be seen, the 2005 dust scheme has increased opacity globally, particularly in the southern hemisphere poleward of around 40° S.

Figure 3 shows the effect of this increased dust opacity on the atmospheric temperature at varying latitudes in Mars’ southern hemisphere. The increased dust scheme results in increased middle atmosphere warming, particularly over the poles, and especially over the north pole. The increased temperature can be attributed to the radiative effects of dust, unlike the current UK version of the model. Strong temperature inversions can be seen close to the ground in the model simulations, but these are not apparent in the MCS or MCD profiles, as they are too close to the surface to be resolved by the instruments.

As can be seen immediately, the profiles from the simulation with the new dust scheme and the assimilation are in much closer agreement with the MCS observations than the profile from the MCD. The lower temperatures close to the pole in the simulation are apparent, but the middle atmosphere warming agrees well with the MCS plot.

Plots of the meridional mass streamfunction (MMS) averaged over an entire Martian year are shown in Figure 4. The MMS from both the simulations and the modelled data from the Mars Climate Database (MCD) shows the dominance of the northern hemisphere circulation through the entire year, consistent with the data from the MCD is not as strong as that from the assimilation. The two simulations using the 2003 and 2005 dust schemes do show stronger southerly circulation than that from the MCD, but it is still weaker than in the assimilation.

As well as comparing the two simulations with each other, we have also carried out comparisons with observations from the MCD and modelled data from the MCD, which is used as a convenient summary of model experiments from the LMD MGCM. Figure 5 shows mean vertical profiles of temperature at varying latitudes from (a) MY24 simulation using 2003 dust scheme; (b) MY25 simulation using 2005 dust scheme; and (c) modelled data from the MCD v3. Panel (d) from [9].

Above around 40 km, there is no data from the TES, and so the profiles are less secure. Even so, it can be seen that the assimilation of volatiles improves the output of the MCD. This can be expected as the assimilation includes the radiative effects of dust, unlike the current UK version of the model. Strong temperature inversions can be seen close to the ground in the model simulations, but these are not apparent in the MICS or MCD profiles, as they are too close to the surface to be resolved by the instruments.

Figure 5 compares the temperature profile near the south pole in more detail. As can be seen immediately, the profiles from the simulation with the new dust scheme and the assimilation are in much closer agreement with the MCD observations than the profile from the MCD. The lower temperatures close to the pole in the simulation are apparent, but the middle atmosphere warming agrees well with the MCD plot.

Project aims

The project will model the Martian water cycle, including radiatively active water ice clouds, to interpret new observations from MCS. We will be using the latest version of the LMD MGCM, which includes the new LMD physics routines. A unique data assimilation system [10] will be used to obtain a complete, dynamically self-consistent reconstruction of the extraterrestrial circulation for the complete period of the MCD mission to date. A series of diagnostic studies will be made to characterise the climatology and synoptic meteorology of Mars over seasonal and interannual timescales, including detailed case studies of events such as the formation of cycloids and weather systems. The assimilation results can be used to test the validity of the new cloud schemes introduced to the model, improving our understanding of the Martian water cycle.
