A reflection mechanism for generating spin-transfer torque is proposed. It is due to interference of bias-driven nonequilibrium electrons incident on a switching junction, with the electrons reflected from an insulating barrier inserted in the junction after the switching magnet. It is shown, using the rigorous Keldysh formalism, that this out-of-plane torque $T_\perp$ is proportional to an applied bias and is as large as the torque in a conventional junction generated by a strong charge current. However, the charge current and the in-plane torque $T_\parallel$ are almost completely suppressed by the insulating barrier. This junction thus offers the highly applicable possibility of bias-induced switching of magnetization without charge current. © 2012 American Institute of Physics. I. INTRODUCTION

Slonczewski proposed a new method of switching the magnetization direction of a thin film by means of a spin-polarized current. The current is spin-polarized by passing through a thick polarizing magnet (PM), whose magnetization is assumed to be pinned, subsequently passing through a nonmagnetic metallic spacer layer of atomic planes, and then through a thin magnetic switching layer (SM) into a nonmagnetic lead. We shall assume that the PM is semi-infinite and that its magnetization lies in the $xz$ plane at an angle $\theta$ to the $z$ axis. The magnetization of the SM is assumed to be parallel to the $z$ axis. The spin-polarized current (spin current) is partly or fully absorbed by the SM, and the corresponding torque exerted on the SM can either switch its magnetization completely or lead to steady-state precession of the magnetization. The current-induced precession of magnetization results in microwave generation. Both effects have great potential for applications, but the current density required for magnetization switching in a conventional junction, shown schematically in Fig. 1(a), is at present too large for commercial applications.

It is easy to see that there is an upper limit on what can be achieved with conventional switching junctions. The maximum spin current is obtained when all carriers are 100% spin polarized, and typical epitaxial junctions are already quite close to this theoretical limit. One way to reduce the current flowing through the switching magnet is to use a three-terminal device. However, a strong charge current still needs to be passed between the electrodes not involved in switching. The quest for a system in which no strong charge current flows anywhere in the system thus continues. An early interesting observation was that, in a junction in which both magnets are perfect polarizers, the torque per unit current diverges when the magnets are anti-parallel. However, these restrictions render this result of little practical value in the context of current-induced switching. A most recent development is the generation of spin current by magnons excited in a magnetic insulator. See, for example, Ref. 6 and the references therein. While this approach appears to be very promising, it is entirely different in spirit to the method proposed here.

We propose that a very large reduction of the switching current can be achieved with a modified two-terminal junction shown in Fig. 1(b). The fundamental difference here is that a thin insulating layer is inserted between the switching magnet and the right lead. The charge current in such a junction is strongly reduced, since it has to pass through a tunneling barrier.

However, we shall show that one of the components of the spin current in the nonmagnetic spacer layer is only weakly affected by the barrier and remains large, even when the barrier is thick. One can, therefore, generate a large spin-transfer torque with a very weak charge current.

II. CALCULATION METHOD

To calculate it, we shall use a rigorous theory of the spin current based on the Keldysh nonequilibrium formalism applied to a single-orbital tight-binding model with nearest neighbor hopping $t$ and atoms on a simple cubic lattice. Generalization to a fully realistic band structure is straightforward and is described in Ref. 7. The Keldysh formalism gives us a completely rigorous prescription of how to calculate the steady-state spin and charge current from the equilibrium-retarded one-electron Green’s functions $g_L$ and $g_R$ at the left and right surfaces of a junction cleaved between the planes $n - 1$ and $n$. It follows, from Ref. 7, that the total spin current between atomic planes $n - 1$, $n$ is the sum of the equilibrium (zero bias) term $j_0^\varphi$ and nonequilibrium (transport) term $j_n^\varphi$,

$$j_0^\varphi = \frac{1}{4\pi} \sum_k \int d\omega \text{ReTr} \left\{ (B - A) \sigma \right\} f(\omega - \mu_L) + f(\omega - \mu_R),$$

(1)
librium interlayer exchange coupling. It should be noted that all occupied electron states contribute to the equilibrium transport contribution to the spin current. Fermi surface contribute, i.e., the term in Eq.(2) is the non-conserved, we drop the subscript $j$. In zero bias, only the equilibrium component of the spin current transports out-of-plane torque.

III. GENERAL COMMENTS

In this paper, we use a conventional method of generating spin currents by applying a bias to a magnetic junction. In zero bias, only the equilibrium component of the spin current $j_{tr}^n$ perpendicular to the plane determined by the PM and SM magnetizations ($xz$ plane) is nonzero. It gives the equilibrium interlayer exchange coupling. It should be noted that all occupied electron states contribute to the equilibrium coupling, which is why Eq. (1) involves the integral with respect to energy. However, the equilibrium term in Eq. (1) makes no contribution to the spin current linear in the bias, i.e., to first order in $V_b$. In the context of current-induced switching, we can thus ignore this term and focus on the transport contribution given by Eq. (2). To the lowest order in the bias (linear response), the Fermi functions in Eq. (2) are expanded to first order in $V_b$, and evaluating it at the common zero-bias chemical potential $\mu_b$. This shows explicitly that only states at the Fermi level incident from the left are strongly reflected at the SM/INS interface. The incident and reflected electron waves interfere to form almost perfect standing waves. To a very good approximation, they are described by a real wavefunction $\Psi$ with components $\psi_j$ and $\psi_{\bar{j}}$. (Note that $\Psi$ is never strictly real. It would be real only for an infinitely high insulating barrier, in which case the junction would cease to be a nonequilibrium system.) Since $j_{tr}^n \propto \Im(\psi_j^\dagger \psi_{\bar{j}} - \psi_{\bar{j}}^\dagger \psi_j)$ and $j_{tr}^w \propto \Re(\psi_j^\dagger \psi_{\bar{j}} - \psi_{\bar{j}}^\dagger \psi_j)$, it is obvious that the corresponding $j_{tr}^w$ vanishes identically for real $\Psi$. The same argument applies to the charge current. On the other hand, $j_{tr}^w$ is nonzero for a standing wave. It follows that the charge current and $j_{tr}^w$ are strongly suppressed by the insulating layer, but we expect that $j_{tr}^n$ remains large and can even be enhanced by the insulating “reflector”. We emphasize that, for this effect to occur, it is crucial that the “reflector” is placed behind the switching magnet. This is essential, because incident and reflected electrons must travel across the whole trilayer and feel spin-dependent potentials of both the PM and SM. We call the junction in Fig. 1(b) a reflecting junction.

The total spin transport current can be again evaluated from Eq. (2), where the surface Green’s functions $g_L$ and $g_R$ now include the effect of electron reflections at the SM/INS interface. In Fig. 2, we plot the spin currents $j_{tr}^n$ and $j_{tr}^w$ and the charge current $j_c$ as a function of the insulating barrier thickness $N_{\text{INS}}$. The angle between the magnetization of the PM and SM layers is taken to be $\pi/2$, and the thickness of the SM is 5 atomic planes. We have used the following

$$j_{tr}^n = \frac{1}{2\pi} \sum_{k_i} d\omega \text{Re} \text{Tr} \left\{ \left[ g_L t A B g_R^\dagger t^\dagger - A B \right] \left[ f(\omega - \mu_L) - f(\omega - \mu_R) \right] + \frac{1}{2} (A + B) \sigma \right\}$$

Here, $A = [1 - g_R t^\dagger g_L t]^{-1}$, $B = [1 - g_R t^\dagger g_L^\dagger t^\dagger]^{-1}$, and $f(\omega - \mu)$ is the Fermi function with chemical potential $\mu$ and $\mu_L - \mu_R = eV_b$. The summation in Eqs. (1) and (2) is over the in-plane wave vector $k_i$, and $\sigma$ is the Pauli matrix. The charge current is calculated by replacing $\sigma$ with the unit matrix. Since we only consider $j_{tr}^n$ in the spacer where it is conserved, we drop the subscript $n$.

FIG. 2. (Color online) In-plane ($j_{tr}^n$) spin current, out-of-plane ($j_{tr}^w$) spin current, and charge current ($j_c$) in the spacer as a function of the insulating barrier thickness. The magnetizations of the PM and the SM are perpendicular. A conventional junction corresponds to $N_{\text{INS}} = 0$. 
values of tight-binding on-site potentials measured in units of $2t$: $-2.3$ and $-2.8$ for the majority and minority spin in the PM and in the SM, $-2.0$ in the spacer and the lead, and $-3.1$ in the insulating barrier. The thickness of the spacer is $N = 12$ atomic planes. Such a choice of parameters models a Co/Cu/Co junction with a good matching of Co majority band with the Cu bands. For comparison, we include, in Fig. 2 also, the results for a conventional switching junction corresponding to the insulating barrier thickness $N_{\text{INS}} = 0$.

**IV. DISCUSSION OF RESULTS**

It can be seen that, for a conventional junction ($N_{\text{INS}} = 0$), the in-plane and out-of-plane spin currents are comparable in magnitude. However, the situation changes dramatically when a “reflector” is inserted behind the switching magnet and the right lead. The in-plane component $j_{\text{tr}}^i$ and the charge current decrease exponentially with the barrier thickness, but the out-of-plane component $j_{\text{tr}}^m$ saturates to a finite value, which is quite close to the value of $j_{\text{tr}}^m$ (and $j_{\text{tr}}^m$) for a conventional junction. To understand these results, it is important to note that there are two different contributions to the out-of-plane spin current $j_{\text{tr}}^m$ in the NM spacer. The first contribution is associated with the tunneling charge current, which carries with it an out-of-plane spin current component. This is the usual out-of-plane component of the spin current, which is observed in conventional switching junctions. It is proportional to the charge current and, thus, decreases exponentially with the barrier thickness.

The second (interference) contribution to $j_{\text{tr}}^m$ arises from interference between the incoming and reflected electron waves. It is shown in Fig. 2 as triangles. It can be seen that it is the only contribution that remains finite for a thick insulating layer. It arises because the bias-driven electrons are almost totally reflected at the SM/INS interface, and therefore, almost perfect standing waves are formed in the NM spacer. The origin of the out-of-plane spin current can then be explained using the following simple model of a standing wave:

$$\Psi = \begin{pmatrix} A_1 \cos(k_\perp y) \\ A_1 \cos(k_\perp y + \phi) \end{pmatrix},$$

where the coefficients $A_1$ and $A_2$ are real, $k_\perp$ is the perpendicular wave vector in the NM spacer, and $y$ is the position in the spacer. The phase shift $\phi$ between the majority- and minority-spin wave functions is a function of $k_\perp Na$, where $N$ is the spacer thickness and $a$ is the lattice constant. The phase shift results in an out-of-plane component of the spin current

$$j_{\text{tr}}^m = k_\perp A_1 A_2 \sin(\phi).$$

For a given electron state with a parallel wave vector $k_\parallel$, the interference contribution to the total out-of-plane spin current oscillates around zero as the spacer thickness increases. The oscillation period is given by $\pi/k_\perp (k_\parallel)$. The total $j_{\text{tr}}^m$ is obtained by summing over all $k_\parallel$ states in the 2D Brillouin zone (see Eq. (2)). States with different $k_\parallel$ have different oscillation periods and, therefore, interfere destructively. It follows that the oscillation amplitude of the integrated interference component of $j_{\text{tr}}^m$ decreases with increasing spacer thickness. The total out-of-plane spin current is thus expected to oscillate with a decaying amplitude about a small constant background determined by the tunneling component. Since the magnitude of the spin current in the spacer of a reflecting junction decreases with the spacer thickness, we need to establish that, for a realistic bias and realistic spacer thickness, the resultant torque on the switching magnet is at least as large as in a conventional junction and also that the transport torque $T_{\text{tr}}^m$ is stronger than the equilibrium interlayer coupling torque $T_{\text{tr}}^0$. The torque exerted on the switching magnet is the difference between the spin currents in the spacer and right lead. To evaluate the torque, we note that the transport spin current in the right lead has only the tunneling component of $j_{\text{tr}}^m$, which is negligible compared with the interference component of $j_{\text{tr}}^m$ in the spacer. The equilibrium spin current $j_{\text{tr}}^0$ in the lead is strictly zero. It follows that both torques $T_{\text{tr}}^m$ and $T_{\text{tr}}^0$ are given by the corresponding spin currents in the spacer. The fact that $T_{\text{tr}}^m$ is stronger than the equilibrium coupling torque $T_{\text{tr}}^0$ with the equilibrium spin current $j_{\text{tr}}^0$ in the lead is strictly zero.

Both torques oscillate with decreasing amplitude as the thickness of the spacer increases. However, the amplitudes, periods, and decay rates of the equilibrium and transport torque oscillations are quite different, which clearly demonstrates their fundamentally different origins. We first note

![FIG. 3.](image-url) Interlayer coupling torque ($T_{\text{tr}}^m$) and transport torque ($T_{\text{tr}}^0$) as a function of the NM spacer thickness when the magnetization of the PM and SM are orthogonal and the applied bias is $V_b = 0.01$ V. The units are assuming a bandwidth $w$ of $6$ eV (i.e., $t = 0.5$ eV).
that, even for the very low bias of $V_b = 0.01\, \text{V}$, the transport torque is much stronger than the coupling torque. There is, therefore, no problem in overcoming the static coupling term by the bias-dependent transport term. Moreover, since the two torques oscillate with different periods, one can always select a spacer thickness where the static coupling is close to zero and, thus, eliminate this term altogether.

We now briefly discuss the oscillation periods and decay rates of $T_{0\parallel}$ and $T_{0\perp}$. It is well known\(^\text{11}\) that the static torque $T_{0\parallel}$ decays as $1/N^2$, where $N$ is the thickness of the spacer. The corresponding oscillation period is given by the spacer Fermi surface (FS) spanning vector\(^\text{11}\) (2 atomic planes in our case). The periods obtained from the extrema of the spacer FS are the only periods that can occur for the equilibrium coupling torque.\(^\text{11}\) However, the transport torque can also oscillate with additional periods arising from sharp cutoffs of the sum over $k_F$ in Eq. (2) (the cutoff periods are removed from the equilibrium coupling term by the energy integral in Eq. (1))\(^\text{12}\). The origin of the cutoff periods was discussed by Mathon et al.\(^\text{12}\) in the case of charge current oscillations, and the same arguments apply here. Finally, the decay of the transport torque oscillations with spacer thickness should be slower than the $1/N^2$ decay rate of the static coupling. This is because the additional destructive interference that arises from the energy integration in the static coupling term (Eq. (1)) is not present in the transport term (Eq. (2)). In the case shown in Fig. 3, the oscillation period of the transport torque $T_{0\parallel}$ is clearly dominated by a cutoff period, which is $4\pi$ atomic planes for the potentials we have chosen. The decay rate of $T_{0\parallel}$ is slower than that of the coupling torque (see, e.g., Ref. 12.)

Finally, we point out that, although our results are for a switching (SM) thickness of 5 atomic planes, qualitatively similar results are obtained for other SM thicknesses. Varying the thickness of the SM has only a small effect on the transport torque $T_{0\parallel}$, i.e., it oscillates with a small amplitude around a finite constant background as the SM thickness increases. This is because most of the interference responsible for $T_{0\parallel}$ occurs in the spacer.

V. CONCLUSIONS AND GENERAL DISCUSSION

The reflecting junction we propose offers huge potential advantages over the conventional junction. Firstly, a strong out-of-plane spin-transfer torque can be generated by an applied bias without the accompanying charge current. The bias strength is not limited to the linear-response regime considered here. Generalization to a strong bias simply requires energy integration in Eq. (2) between $\mu_L$ and $\mu_R$. The applied bias is then limited only by the barrier height. The second advantage of the reflecting junction is that the magnitude and sign of the ratio $T_{0\parallel}/T_{0\perp}$ can be tuned by the height/width of the reflecting barrier and by the spacer thickness. This is important, since the ratio $T_{0\parallel}/T_{0\perp}$ controls switching scenarios.\(^\text{13}\) For example, with the appropriate sign of this ratio, microwave generation can be achieved without an applied magnetic field.\(^\text{14}\)

A bias controlled switching was proposed earlier in Ref. 15. However, the physical mechanism behind this idea is completely different. It is based on a bias-induced modification of the equilibrium interlayer coupling and ignores completely the transport term considered here. However, as already discussed, the modification of the equilibrium coupling by a bias is a higher order effect, which vanishes to the first order in the bias.

Since the out-of-plane torque $T_{0\parallel}$ arises from interference between incident and reflected electron waves, one needs good interfaces to observe and exploit it. However, the quality of the interfaces need not be any better than that required for observation of the usual interlayer exchange coupling, which is also an interference effect. In addition, the quality of the SM/INS interface may also be important. However, since the main role of the insulator is to suppress the charge current, the quality of this interface may not be so crucial. Furthermore, it is known from experiments on tunneling junctions with a MgO barrier that the Fe/MgO interface can be grown almost perfectly epitaxial, and we suggest that this combination would be an ideal choice for the reflecting junction.

Finally, we would like to mention that an insulating barrier could be replaced by a doped semiconductor layer, such as InAs, which forms an ohmic contact with SM (e.g., Fe). This might allow a finer tuning of the ratio $T_{0\parallel}/T_{0\perp}$, since the spin current $T_{0\parallel}$ that can flow through the junction could be controlled by doping (size of the semiconductor FS).

Recently, there has been some interest in the use of magnetic insulators as components in conventional switching junctions.\(^\text{16,17}\) However, these references are not directly relevant to our system, since they do not consider electron interference in a non-magnetic spacer, which is essential for the operation of the device described here. In particular, the mixing conductance approach of Ref. 16 cannot be used to calculate interference effects. Considering our junction, it might be possible to replace the switching magnet/insulator part of the structure with a magnetic insulator. However, the properties of such a junction are currently unknown and require further investigation.
