ABSTRACT

We present Herschel images from the HOBYS key program of the Eagle Nebula (M 16) in the far-infrared and sub-millimetre, using the PACS and SPIRE cameras at 70 μm, 160 μm, 250 μm, 350 μm, 500 μm. M 16, home to the Pillars of Creation, is largely under the influence of the nearby NGC 6611 high-mass star cluster. The Herschel images reveal a clear dust temperature gradient running away from the centre of the cavity carved by the OB cluster. We investigate the heating effect of NGC 6611 on the entire M 16 star-forming complex seen by Herschel including the diffuse cloud environment and the dense filamentary structures identified in this region. In addition, we interpret the three-dimensional geometry of M 16 with respect to the nebula, its surrounding environment, and the NGC 6611 cavity. The dust temperature and column density maps reveal a prominent eastern filament running north-south and away from the high-mass star-forming central region and the NGC 6611 cluster, as well as a northern filament which extends around and away from the cluster. The dust temperature in each of these filaments decreases with increasing distance from the NGC 6611 cluster, indicating a heating penetration depth of ~10 pc in each direction in 3–6 × 10^22 cm^2 column density filaments. We show that in high-mass star-forming regions OB clusters impact the temperature of future star-forming sites, modifying the initial conditions for collapse and effecting the evolutionary criteria of protostars developed from spectral energy distributions. Possible scenarios for the origin of the morphology seen in this region are discussed, including a western equivalent to the eastern filament, which was destroyed by the creation of the OB cluster and its subsequent winds and radiation.

Key words. ISM: clouds – ISM: structure – dust, extinction – stars: early-type – stars: protostars

1. Introduction

Forming in dynamic and ever-changing environments, high-mass stars are complex entities which, through radiation and stellar winds, heavily impact their natal environments, possibly even triggering the formation of new stars and planetary systems. A general rarity of candidates and their rapid evolutions mean that it is difficult to characterise the early evolutionary stages of high-mass stars (cf. Garay & Lizano 1999).

The Herschel Space Observatory (launched 2009; Pilbratt et al. 2010) has already had a significant impact on star formation studies, owing primarily to the large key programs devoted to this field, specifically the Herschel imaging study of OB Young Stellar objects (HOBYS; Motte et al. 2010) and Gould Belt Survey (André et al. 2010), as well as the Hi-Gal survey (Molinari et al. 2010). These programs target the natal environments of burgeoning young stars, such as interstellar filaments and ridges (Arzoumanian et al. 2011; Hill et al. 2011), as well as sources embedded within them, e.g., prestellar cores
and protostars (Bontemps et al. 2010; Henkemann et al. 2010; Giannini et al. 2012), and investigate the impact of OB stars on cloud formation (Zavagno et al. 2010; Schneider et al. 2010). The primary HOBYS\(^1\) driver is to compile an unbiased census of high-mass star progenitors, and their natal ridges, in the nearest (<3 kpc) star-forming complexes (Motte et al. 2010), one of which is M 16.

The Eagle Nebula (M 16) is a young (1–3 × 10\(^6\) yr; Hillenbrand et al. 1993), active high-mass star-forming region in the constellation of Serpens ~2 kpc from the Sun. M 16 was first observed by de Cheseaux in 1745 and then rediscovered by Messier in 1764 who was the first to comment on its nebulosity. The European Space Agency’s (ESA’s) Infrared Space Observatory (ISO; Cesarsky et al. 1996) revealed the presence of unusually hot dust in the core of the nebula (Pilbratt et al. 1998, \(T_{\text{colour}} \sim 200\) K). But it was the Hubble Space Telescope images of its ionised gas (Hester et al. 1996), better known as the “Pillars of Creation”, that has made M 16 iconic and one of the most observed objects in the sky.

M 16, and especially these pillars, has since been observed at many wavelengths spanning the electromagnetic spectrum, as well as in many dedicated spectral line studies (e.g., Pound 1998; White et al. 1999; Allen et al. 1999; Urquhart et al. 2003; Linsky et al. 2010), as part of the HOBYS key program (Motte et al. 2010). M 16 was observed on 2010 March 24 and 2010 September 11–12, as part of the HOBYS key program (Motte et al. 2010).

In March, the SPIRE (250 \(\mu\)m, 350 \(\mu\)m, 500 \(\mu\)m; Griffin et al. 2010) camera was inadvertently turned off and thus only the shorter PACS (70, 160 \(\mu\)m; Poglitsch et al. 2010) wavelengths were mapped during this period. In September, the parallel-scan mode of Herschel was used to map simultaneously with both instruments at the aforementioned five bands, using the slow scan speed (20′/s). For these September observations, the SPIRE camera was aligned with the PACS data taken from March, allowing 100% common area coverage (normally, the positional offset between the PACS and SPIRE instruments results in a small (20′) spatial offset between the PACS and SPIRE maps), as well as an extended PACS coverage to the east and south (see Fig. A.1, top). A total area of ~1.5 deg by 1.5 deg was mapped using two orthogonal scan directions.

Each of the March and September data were reduced with version 5.0.1975 of the Herschel Interactive Processing Environment (HIPE\(^2\); Ott 2010) adopting standard steps of the default pipeline to Level 1 products including calibration and deglitching. To improve the baseline subtraction, data taken during the turn-around of the telescope were used. Calibration of the PACS data has been found to be within 5%, whilst SPIRE calibration is within 10% for all bands (see the respective observers’ manuals).

Maps were produced using the HIPE Level 1 data and v7 of the Scanamorphos software package\(^3\) which performs baseline and drift removal before regriding (Roussel 2012). The two sets of PACS data, from March and September, were combined within Scanamorphos using the “galactic” option, to produce a single map of the entire PACS coverage. For simplicity, we hereafter use PACS data to refer to the combination of the two individual PACS observations, rather than referring to one particular data set. The individual Herschel images at each wavelength can be found in Fig. A.1, including the highest resolution 70 \(\mu\)m image which traces the hot dust and protostars in this region. The three colour image of the the entire M 16 complex, as well as a zoom to the central region around the OB cluster is given in Fig. 1.

### 3. Structural analysis

The Herschel maps of the Eagle Nebula show bright emission throughout, particularly around the NGC 6611 cluster (see Figs. 1 and A.1). This bright emission covers the Pillars of Creation and the Spire\(^4\) east of the cluster and a possible ridge (see Sect. 3.3) of material to the north-west.

Immediately to the north of this ridge is a prominent arch-like structure (see Fig. 1, left). While weak diffuse emission can be seen towards this arch-like structure in the infrared (8 \(\mu\)m; see Fig. 5 of Indebetouw et al. 2007), it is much more visibly striking and associated with a clear density enhancement in our Herschel images e.g., Fig. 1, right (see also Figs. 2 and 3 below). To the south-west of the ridge is the massive YSO (MYSO) identified by Indebetouw et al. (2007, also known as IRAS 18152-1346) as the most luminous YSO (1 × 10\(^5\) \(L_\odot\)) in the region. The Herschel images of M 16 indicate many other sites of star formation, such as small clusters of sources in the south-east of the map, which are more easily identified in the higher resolution PACS data (see Fig. A.1, top).

\(^{2}\) http://herschel.esac.esa.int/HP&E_download.shtml

\(^{3}\) http://www2.iap.fr/users/roussel/herschel/index.html

\(^{4}\) The Spire is a well known region in the Eagle Nebula. See, http://en.wikipedia.org/wiki/Messier_16
The three-colour composite image of this region (Fig. 1) shows a very distinct temperature gradient away from the NGC 6611 cluster. This temperature gradient is reminiscent of that seen in other HOBYS regions such as RCW 120 (Zavagno et al. 2010) and the bubble H ii region study of Anderson et al. (2012).

3.1. Column density and dust temperature maps

The dust temperature and column density (N(H2)) maps of M 16 were drawn by fitting, pixel-by-pixel, spectral energy distributions (SEDS) using a modified blackbody model (Hill et al. 2009, 2010), following the procedure outlined by Hill et al. (2011). These data were convolved to the resolution of the 500 μm band (37″), and the zero offsets, which were determined from comparison with Planck and IRAS following the procedure detailed by Bernard et al. (2010), were applied to the individual maps prior to fitting. Only the four longest Herschel wavebands, which trace cold dense material, were used to make the column density and dust temperature maps (Fig. 2), a method consistent within the HOBYS programme (Hill et al. 2011; Nguyen Luong et al. 2011). The 70 μm emission is excluded from the
fits as it is not tracing the cold dust that we are most interested in, and is likely tracing small grains in hot PDRs instead (cf. Fig. 3). Furthermore, excluding the 70 μm emission ensures that the SED fit is more robust, since the 70 μm flux does not completely fit a single temperature greybody model dominated by longer wavelength fluxes. We used a dust opacity law in which the dust opacity per unit mass column density (κν), is given by κν = 0.1 (ν/1000 GHz)β cm2/g (e.g., Motte et al. 2010), and a dust spectral index of β = 2. The latter was fixed in line with the literature (Goldsmith et al. 1997, and references therein) and because we do not have longer wavelength (sub)millimetre data to constrain β accurately. The quality of a SED fit was assessed using χ² minimisation. Most of the individual single temperature SED fits comprising the dust temperature and column density maps peaked around, or longward of, the 160 μm flux – the shortest wavelength data used in the fit. The observed rms of cirrus noise in the derived column density map is ~2 × 10²¹ cm⁻² (Av ~ 2 mag). Note however, that the column density and dust temperature are line of sight measures.

The median temperature throughout M 16 is ~18 K, with slightly cooler temperatures in the northern part of the Herschel map, which is furthest from the Galactic plane. The eastern portion of M 16 is dominated by a dense filament (3–7 × 10²² cm⁻²) situated directly east of, and running parallel to the Pillars of Creation. This “Eastern Filament” appears as a cool temperature depression (~16 K; Fig. 2, right, see Sect. 4.1) with respect to the warmer surrounding material.

Figure 3, a three colour composite of the column density, dust temperature and 70 μm image, highlights the region affected by strong PDR emission, i.e., the interface between the cloud and the cavity swept out by the NGC6611 cluster. The inclusion of the 70 μm emission here highlights clear examples of limb brightening, where the filamentary structures around the cavity have heated edges at the ionisation front created by the NGC6611 cluster. Furthermore, this Figure demonstrates the strong correspondence between high column density and low temperature, especially with respect to the Eastern Filament (clearly visible here in red).

3.2. Filamentary structure

Recent Herschel observations have revealed the ubiquity of interstellar filaments, especially in star-forming regions. André et al. (2010, 2011) proposed that in low-mass star-forming regions only those filaments above an Av of ~7 mag are gravitationally unstable (supercritical) and thus capable of forming prestellar cores in their interiors. In fact, a large portion of the molecular complexes observed as part of HOBYS are above this star-forming threshold (e.g., Hill et al. 2011; Nguyen Luong et al. 2011; Schneider et al. 2012).

To take a census of the filaments in the M 16 star-forming complex, the DisPerSE algorithm (Sousbie 2011; Sousbie et al. 2011) was applied to the column density map. DisPerSE works with Morse theory and the concept of persistence to identify topological structures (see Sousbie 2011, for a detailed explanation of these concepts) such as filaments and ridges, and connect their saddle-points with maxima by integral lines. This algorithm has already been successfully applied by our group to trace filamentary structures in star-forming regions (e.g., see Hill et al. 2011; Peretto et al. 2012). The crest points of the filaments, as identified by DisPerSE are presented in Fig. 4.

The southern half of M 16 is dominated by two main filaments which run roughly parallel to each other near the centre of the Herschel map, before converging to a solitary filament.
than the western one. The Pillars of Creation lie on a filament 5, a factor of $-18$ 18.8. The filaments are plotted as a function of their projected distance from the cluster. The NGC 6611 cluster is located at "0" on the $x$-axis, centred at 18 18.8 $\pm$13.49. The green dashed line on the dust temperature (top) is the dust temperature after removing the effects of cold sources within the filaments, following the relation of Juvela & Ysard (2011; Fig. 1, see footnote 6 and also Didelon et al., in prep., who examine this relation for Herschel filaments). The thick vertical lines seen on the profile of the Northern Filament indicates structures at the same distance from the cluster, as the filament tends to curve around the cavity.

Since the arch appears weak at 8 $\mu$m (with IRAC; see Indebetouw et al. 2007, Fig. 5), and not as clearly as in our Herschel images (see for example Figs. 1 and A.1 and Sect. 3), it is likely composed of mostly cool material. At the base of the arch is a potential ridge of material. Hill et al. (2011) define a “ridge” as a high-column density ($\sim10^{23}$ cm$^{-2}$) super-critical filament dominating its environment that is capable of forming high-mass stars. The most prominent part of the Northern Filament has a column density above 1.0 $\times$ 10$^{23}$ cm$^{-2}$ over $\sim$2 pc. It is not as dominant, i.e., containing most of the material in the vicinity, as the Vela C ridge or DR 21 ridge (Hill et al. 2011; Hennebmann et al. 2012, respectively). This ridge and its star formation content is discussed by White et al. (in prep.).

3.3. The arch and a potential ridge

In the individual Herschel images of the Eagle Nebula there is clear evidence of a arch-like structure to the north-west of the NGC 6611 cluster (Figs. 1 and A.1). This arch-like structure is actually composed of two arches, an inner warmer ($\sim$17–20 K) arch, and an outer high column density ($\sim$2.0–$5.8 \times 10^{22}$ cm$^{-2}$) arch. These two arches may in fact be tracing different parts of the same shell-like structure or bubble, as discussed below in Sect. 5.1. These structures are more prominent at the shorter PACS wavelengths. Due to its tendency of tracing density crests, DisPerSE only traces the column density arch (see, Fig. 4).

5 Note that DisPerSE identifies a single filament for thee pillars, from the column density crest points. This is simply a limitation of the column density map, as at 37$''$ resolution only the densest (western most) pillar is detected (see Fig. 2, right).

4. Impact of the NGC 6611 cluster on the M 16 cloud

The NGC 6611 cluster is responsible for most of the mechanical and radiative energy incident on the molecular cloud complex around the Eagle Nebula (M 16). Here we assess the dust heating effects in view of constraining the geometry of the complex.

4.1. The cold Eastern Filament

The Eastern Filament is a cold prominent filament running east of the NGC 6611 cluster in the column density and dust temperature maps (Figs. 2–4). This southern portion of this filament houses many 70 $\mu$m sources (see Fig. A.1, top-left), that we interpret as embedded protostars.

In order to determine how the presence of the OB cluster in M 16, in particular its heating effect, has impacted the Eastern Filament, column density and dust temperature profiles were taken along the filament. These profiles were derived using the crest points identified by the DisPerSE algorithm (see Sect. 3.2), and are presented in Fig. 5 (left) as a function of projected distance from the cluster. The dust temperature profile of the Eastern Filament shows a decreasing temperature with near the southern edge of the map. The eastern one (“Eastern Filament”, see Sect. 4.1, Fig. 4) is much more prominent (by a factor of $>2$ with respect to column density, see also Fig. 2, left) than the western one. The Pillars of Creation lie on a filament$^5$, which joins the aforementioned Western Filament (see Fig. 4).

The northern half of the M 16 region, just north of the central NGC 6611 cluster, displays a complex and clustered network of filaments. The most coherent filament in this region starts close to the NGC 6611 cluster, connects to the ridge and thereafter heads north-west (see Fig. 4). We hereafter call this filament the “Northern Filament” – see Sect. 4.2.

Interestingly the clear 70 $\mu$m filaments, seen to the south-east (see Fig. A.1, top-left), which highlight PDR or low column density filaments, are generally perpendicular to the main SE-NW direction of the cloud and the major filaments (see Fig. A.1, top-left). These 70 $\mu$m emission features are not associated with point like emission of YSOs, but rather to heating/UV ionisation of cloud edges, such as limb brightening/PDRs. These filaments are similar to the striations seen in regions such as Taurus (Palmeirim et al., in prep.).
increasing distance from the OB cluster. There are small fluctuations along the temperature profile, which are anti-correlated with column density (see the lower panel of Fig. 5) and thus density enhancements such as star-forming sources located within the filament. Around ~17 pc from the OB cluster the temperature of the Eastern Filament stabilises as it approaches the southern edge of the map. At distances >17 pc, the dust temperature in the Eastern Filament increases with increasing distance as it approaches the Galactic plane. The Eastern Filament has a ∼3 K temperature gradient over its projected length of ~20 pc.

To remove the contributions of cold dense sources within the Eastern Filament to the dust temperature we have applied a de-screening to the data following the relation⁶ by Juvela et al. (Fig. 1; 2011). This relation (green line on Fig. 5) simulates the temperature structure for a filament with a homogeneous density crest, and and while it removes the effects of density enhancements above $N_{\text{H}_2\text{ ref}}$ (where $N_{\text{H}_2\text{ ref}}$ is taken here as $3.2 \times 10^{22} \text{ cm}^{-2}$) including, cold dense fragments embedded within the filament, it does not remove the centrally heated protostars (indicated as YSOs in Fig. 5). This column density filtering highlights the effect of the OB cluster on the dust temperature of the Eastern Filament as a whole, the overall trend of which is a decreasing dust temperature with increasing distance from the OB cluster up to a projected distance of ~17 pc.

In contrast to the dust temperature, the mean column density profile (Fig. 5, left) appears to remain rather constant with distance from the OB cluster, though it is subject to the aforementioned density enhancements. The strong (and wide) density fluctuation seen at ~20 pc reaching $7 \times 10^{22} \text{ cm}^{-2}$, is located at approximately where the Eastern and Western Filaments appear to meet (see Sect. 3.2).

4.2. The Northern Filament

The Northern Filament originates at the eastern part of the NGC 6611 cavity, runs around the cavity and across the potential ridge (see Sect. 3.3 and White et al., in prep.) before continuing into the northern part of the map (see Fig. 4).

The column density and dust temperature profiles of the Northern Filament are given in Fig. 5 (right). The dust temperature of this filament remains rather constant (∼20 K) around the NGC 6611 cluster, except for a temperature spike at ~3 pc corresponding to a position close to a well known HII region (IRAS 18156-1343). At ~6 pc the dust temperature drops rapidly with increasing distance from the NGC 6611 cluster (5 K over 4 pc), before stabilising at a near constant temperature of ~16 K. This temperature drop is greater than that seen in the Eastern Filament (see Fig. 5, left). This difference is (partly) because the column density profile is less homogeneous than the Eastern Filament, with a large dip in the column density curve due to the presence of the ridge. While the dust temperature used here is a line of sight average for the filament, and the absolute values of the dust temperature are likely to be slightly overestimated as a result, the gradient identified in these Eastern and Northern filaments is still present and robust.

Similarly to the Eastern Filament, a de-screening was applied to the Northern Filament, with $N_{\text{H}_2\text{ ref}}$, the median column density, taken as $4.4 \times 10^{22} \text{ cm}^{-2}$. After applying this de-screening, the dust temperature of the Northern Filament (green line Fig. 5, right) decreases steadily over a much greater distance (5 K over 8 pc). Even after de-screening, the drop in dust temperature is greater than that in the Eastern Filament, which may result from the less homogeneous column density in the Northern Filament or it might also suggest a larger relative inclination along the line of sight, though spectral line (velocity) information is needed to support this idea. Note that at distances >12 pc the de-screening temperature is much lower (∼2 K) than without de-screening. This is likely due to the fact that there are very few dense cores in this portion of the filament (see Fig. 2), and thus the de-screening does not completely apply here.

4.3. NGC 6611 and its immediate surroundings

In order to determine the extent of the heating from the OB cluster on low column density material ($1.5 \times 10^{22} \text{ cm}^{-2}$ or lower, see Fig. 6), PA-averaged radial profiles of both the dust temperature and the column density were taken covering all of the dense star-forming material in the region, as well as the cavity carved out by the NGC 6611 cluster where there is more diffuse
The three-colour composite image of this region (Fig. 1) shows a very distinct temperature gradient running away from the centre of the cavity carved out by the NGC 6611 cluster. Those regions closest to the cluster are subject to heating by the OB stars, which is reflected in the higher dust temperatures (+3–5 K) compared with those regions in the more remote (14–17 pc) parts of the cloud, where the heating no longer penetrates. The temperature gradient from the NGC 6611 cluster is similar to that seen in Rosette (Schneider et al. 2010) but over a smaller distance, with a clear drop in temperature within 10 pc of the cluster in all directions (see Figs. 5 and 6).

The M 16 complex displays evidence of a large number of bright rims, which typically occur close to PDRs, especially in the vicinity of the NGC 6611 cluster (see Figs. 2, right and Sect. 3.2). Whilst a greater investigation into these potential sites of limb-brightening is warranted, we can use the information in these maps to infer the structure relative to the OB cluster (e.g., Minier et al. 2012). Those objects that exhibit signs of bright blue limb-brightening emission at their surface are likely directly receiving incident radiation from the NGC 6611 cluster and are thus at the same distance as the cluster or behind it. There are clear pockets of hot dust (traced by 70 μm emission, shown in blue, in Fig. 1) on the southern side of the NGC 6611 cluster, around the pillars, and to the north of the cluster, as well as inside the arch structure (also seen in Fig. 3). This inner 10 pc shell is suggestive of a three-dimensional geometry where the bright 70 μm objects, such as the Pillars of Creation, are illuminated by the NGC 6611 cluster and not extinguished by any cloud in its foreground. The location of the Spire and the ridge is less clear. On the other hand, objects such as the MYSO, which do not show evidence of bright rims, and thus incident radiation from the cluster, are clearly in front of the cluster, and closer to us along the line of sight.

An interesting question is raised with respect to the origin of the arch structure (Sect. 3.3 and Fig. 4). Is it actually one structure e.g., created by the expansion of radiation similar to that of a bubble, or is it a consequence of morphology? As noted in Sect. 3.3, two arches are in fact detected at this location and DisPerSE only detects the denser of these. Figures 1 and 2 (right) suggest that the inner warmer arch is closer to the cluster, directly influenced by its heating, whilst the outer higher column density arch is likely above (i.e., closer to us along the line of sight) and away from the cluster. This suggests some sort of curved morphology, where the two arches are in fact two sides of a three dimensional shell-like or bubble-like structure, with the near (denser arch) and far (warmer arch) curved sides of the shell/bubble appearing as two arches in two dimensions.

Two prominent filaments are detected in the M 16 complex, a cool dense Eastern Filament (see Sect. 4.1) which spans almost 25 pc, and the Northern Filament (see Sect. 4.2) which extends across the ridge, at the western side of the arch structure, and up to ~15 pc. Figures 2 (left) and 3 indicate a clear branch towards the southern end of the Eastern Filament, at ~15 pc from the origin (see Fig. 5, left), as discussed in Sect. 4.1. DisPerSE (Sect. 3.2) actually detects the much weaker (with respect to column density – Fig. 2) western component of this branch (Fig. 4), which extends up to the base of the Pillars of Creation. If we were to extrapolate or extend this western filament, it would

**Notes.** The parameters of the column density and dust temperature derived from probability distribution functions (PDFs) for each sub-region in M 16 (Sect. B and Fig. B.1) as well as their heating distance and gradient are also given (Fig. C.1). The numbers given in parentheses in the last column is the value obtained when a de-screening has been applied (see Sect. 4.1). The asterisk here (*) indicates that the heating gradient was taken over the steepest portion (3–5 pc), see Fig. C.1.
continue to join the Northern Filament at the approximate location of, and along the same line of sight as, the MYSO. In this scenario, the Eastern Filament has remained largely undisturbed whilst the Western Filament has undergone a dramatic transformation. Once the home of the NGC 6611 cluster, it would have been destroyed as the cluster accumulated mass and formed the high-mass OB stars seen in existence today. The strong ionising winds from the OB stars themselves would have carved out a cavity in this filament, and eradicated any existence of the continuation of this Western Filament. Small grains associated with this Western Filament are still present and emit strongly at 70 μm (Fig. A.1, top-left).

5.2. The heating effect of the NGC 6611 cluster

The high-mass star cluster NGC 6611 has noticeably impacted, in terms of heating, the M 16 complex as a whole. The dust temperature profiles (Figs. 5 and 6) clearly show the effect and the extent of this impact, i.e., how much and how far it has affected the temperature in all directions. Despite the fact that the dust temperature measured at the crest (Fig. 5) or averaged within segments (Fig. 6) obviously depends on the column density of the material traced, the penetration distances do not seem very different from the diffuse emission of segment 1 (<N_H > >10^{22} cm^{-2}) to the high column density emission of the Northern Filament (<N_H > >6 ×10^{23} cm^{-2}). Our analysis (see Figs. 5 and 6 and Table I) has shown that NGC 6611 is able to heat the M 16 cloud to a projected distance of ~8–10 pc. The M 16 cloud displays ~1.5–5 K temperature variations, corresponding to heating gradients of 0.25–0.6 K/pc, with an average value of ~0.3 K/pc. The dust temperature profiles of the Eastern and Northern Filaments (Fig. 5) indicate that NGC 6611 is able to heat, by ~3–5 K, star-forming sites (>10^3 cm^{-3} dense cores) approximately up to 10–11 pc into each filament. While the dust temperature and column density gradients are robust, the absolute values of these quantities are subject to line of sight effects.

It is clear from the radial profiles (Fig. 6) that the heating effect of NGC 6611 is not the same in all directions. These differences would be expected if the NGC 6611 cluster is in fact at the same distance as only some of these regions (as suggested in Sect. 5.1). Alternatively, the ionisation and heating depths of the cluster is simply dependent on the amount of material in the way, such that high column density regions will block the radiation better than low column density regions in which the radiation more easily penetrates.

Herschel observations have shown that interstellar filaments act as the birthplace of star formation. In M 16, we have shown that interstellar filaments can largely be influenced by heating, such as that coming from the nearby high-mass NGC 6611 cluster (e.g., Fig. 5). Such external heating is often not considered when deriving the evolutionary status of a core from its far-infrared SED. Evolution/age proxies such as L_{submm}/L_{bol} (André et al. 2000) or T_{bol} (Myers & Ladd 1993) for evolutionary diagrams have been recently extrapolated to massive dense cores (e.g. Motte & André 2001). These parameters should be taken with caution, since massive dense cores generally form in molecular cloud complexes associated with OB clusters. By ignoring this effect, T_{bol} will appear cooler at larger distances from the cluster, and hotter closer to the cluster. Similarly, the L_{submm}/L_{bol} ratio of a protostellar core will be larger further from the cluster than closer to it.Inferring evolutionary trends from these parameters, one would then naturally find more evolved protostellar dense cores closer to the cluster than further away from it, giving the (incorrect) impression of triggered star formation. In order to avoid these biases, the effects of external heating on interstellar filaments should be considered when determining the evolutionary state of a star-forming core, especially in high-mass star-forming regions.

As an example, a ~6 K dust temperature gradient has been found for massive dense cores forming in the Rosette molecular cloud under the influence of the NGC 2244 cluster (Motte et al. 2010). Even after subtracting a possible 3 K gradient coming from the different temperatures of the cloud filaments inside which prestellar cores have formed and evolved into protostars, the remaining 3 K could still argue for an age trend for these YSOs, as originally suggested by Schneider et al. (2010). Our Herschel data of M 16 do not provide any evidence for a supernova remnant, as suggested by Flagey et al. (2011). Our maps (Fig. 2, right) indicate dust temperatures in M 16 that are consistent with other high-mass star-forming regions (Nguyen Luong et al. 2011; Hill et al. 2011). Flagey et al. (2011), with their shorter wavelength Spitzer data, were more sensitive to hot dust which is being shatted by a supernova remnant. Based on this comparison alone, we are unable to support or refute this claim based on our Herschel data, which are more sensitive to colder dust. However, young supernova remnants such as SN 1987A (Matsuura et al. 2011) and Cassiopeia A (Barlow et al. 2010) have been readily observed by Herschel, as have much older supernova remnants e.g. W44. SN 1987A is seen as a point source with PACS and as extended emission at increasingly longer Herschel wavelengths, while Cas A is well traced at all Herschel wavelengths, as well as at ~24 μm with Spitzer. The fact that we don’t see evidence of such a supernova remnant in our individual Herschel images, and that we see no evidence of impact on the column density distribution around the NGC 6611 cluster, as well as the absence of emission seen with Spitzer (e.g. Flagey et al. 2011; Indebetouw et al. 2007) does not favour the presence of a supernova remnant in this region.

Appendix A: Herschel images of M 16

Fig. A.1. The 5 Herschel wavebands of M 16, from top to bottom, 70, 160, 250, 350 and 500 μm. Note also the extended PACS coverage compared with SPIRE (see Sect. 2). The observed level of cirrus noise in M 16 is ~20 mJy and 200 mJy at λ = 70 and 160 μm, respectively and 2, 1 and 1 Jy at the SPIRE 250, 350 and 500 μm bands. At shorter wavelengths only those warmer objects, such as protostars and HII regions are seen. At longer wavelengths Herschel detects cold, deeply embedded filaments and the progenitors of high-mass stars.
Appendix B: Probability distribution functions

To examine the dust temperature and column density structure in the entire M 16 region probability distribution functions (PDFs) were derived (Fig. B.1). Column density PDFs have been used by many authors to characterise cloud structure based on star formation activity (Kainulainen et al. 2009; Federrath et al. 2010). The column density in M 16 spans almost two orders of magnitude ($5 \times 10^{21} - 3.7 \times 10^{23} \text{ cm}^{-2}$), whilst the dust temperature ranges from 14.5 K to 23.5 K. The highest temperature in the maps is recorded directly west of the base of the Pillars of Creation and thus south of the NGC 6611 cluster.

The sub-region hosting the Pillars of Creation (Fig. B.1, blue) attains higher dust temperatures than the other sub-regions, including that of the Spitzer identified MYSO. This difference shows that the NGC 6611 cluster has had more of an impact on the cloud temperature than the current star formation process. The M 16-N and Spire sub-regions have similar dust temperature PDF slopes (>21 K), which likely reflects their similar distance from the NGC 6611 cluster, though the M 16-N sub-region contains colder gas in the northern part of the region, including the ridge itself. The M 16-NW and M 16-E sub-regions span only small ranges in temperature. The median column density and dust temperature for each sub-region, determined from the PDFs, are given in Table 1.

It is interesting to note that while the M 16-E and Spire sub-regions have similar column density PDF profiles, they display quite different dust temperature PDF profiles. This suggests that they are both a part of the same cloud structure, but that the Spire is closer to and thus more readily externally heated by the NGC 6611 cluster than M 16-E. The three sub-regions closest to the OB cluster (Pillars of Creation, Spire, MYSO) have similar dust temperature profiles, but quite different column densities.

There is no clear trend in the column density PDFs to suggest or represent an effect of the winds or radiation from the NGC 6611 cluster on the sub-regions. The median temperature of each region correlates closely with the projected distance from the cluster, suggesting no strongly unbalanced projection effects for the cloud surrounding the NGC 6611 cluster.

The probability distribution functions (Fig. B.1) confirm that the column density in each sub-region in M 16 is indeed different, which influences the extent of the heating effect of the NGC 6611 cluster on each sub-region, as seen in the dust temperature PDFs. At zero-order and above $A_V > 15 \text{ mag}$ there is no difference seen in the structure of the cloud with distance from the NGC 6611 cluster. That is, the column density PDFs of sub-regions near to the cluster, and thus heavily impacted,

---

3 Where $N_{H_2} = 1 \times 10^{21} \text{ cm}^{-2} \text{ mag}^{-1}$ (Bohlin et al. 1978).
Fig. C.1. Upper left: column density map of NGC 6611 with radial segments as indicated. Upper-middle to lower-right: dust temperature (black) and column density (red) PA-averaged radial profiles in each segment. Segments are arranged clockwise starting with the Pillars of Creation (upper-middle) to the cavity region (lower-right) as identified by numbers. The profiles are the median values with projected distance in each segment to avoid biases by the presence of protostars. The radial lengths of each segment were defined by a drop in column density (as seen in the upper-left panel).

and those in more remote portions of the map, display similar column density PDF slopes.

It is also worth noting, that though normalised, the Pillars of Creation, Spire and MYSO sub-regions are comprised of a small number of pixels compared with the other sub-regions in the complex, which could thus affect their interpretation.

Appendix C: Detailed radial segments around NGC 6611

The radial profiles of more detailed segments (than Fig. 6) around the NGC 6611 cluster, including the Pillars of Creation, can be found in Fig. C.1.
