Abstract—Cellular network planning strategies have tended to focus on peak traffic scenarios rather than energy efficiency. By exploiting the dynamic nature of traffic load profiles, the prospect for greener communications in cellular access networks is evolving. For example, powering down base stations (BS) and applying cell zooming can significantly reduce energy consumption, with the overriding design priority still being to uphold a minimum quality of service (QoS). Switching off cells completely can lead to both coverage holes and performance degradation in terms of increased outage probability, greater transmit power dissipation in the up and downlinks, and complex interference management, even at low traffic loads. In this paper, a cellular network model is presented where certain BS rather than being turned off, are switched to low-powered relay stations (RS) during zero-to-medium traffic periods. Neighbouring BS still retain all the baseband signal processing and transmit signals to corresponding RS via backhaul connections, under the assumption that the RS covers the whole cell. Experimental results demonstrate the efficacy of this new BS-RS Switching technique from both an energy saving and QoS perspective, in the up and downlinks.

I. INTRODUCTION

Despite cellular networks being one of the most fertile wireless communication areas, major concerns persist about future spectrum shortages and critical energy consumption issues due to its inexorable growth, which has far exceeded expectations\(^1\). The rise in wireless network energy consumption is reflected by increasing greenhouse gas emissions, which has been recognised as a serious threat to both environmental protection and sustainable development. Vodafone’s statistical results, for example, show the total energy consumption has reached 4,117 GWh in the 2010/11 base year, which equates to 2.29 millions of tonnes gross CO\(_2\) emissions, with 61% of this being generated by base stations (BS) [1]. The outcome is that not only is this rapid growth in wireless networks impacting upon the economy, but also on the environment. Strategies have been proposed by mobile operators to sustain capacity growth without environmental impact, by designing green communication networks with reduced operational energy consumption together with limits upon energy bills. The European Commission has already acted seeking a 20% cut in CO\(_2\) emissions allied with a 20% improvement in energy efficiency by 2020 [2]. Analogously, some UK mobile phone operators including Vodafone and Orange have announced CO\(_2\) emission reductions in the range 20% to 50% by 2020 [1].

In current cellular networks, both the cell size and capacity are fixed based on the peak traffic loads for every cell, irrespective of either the time of day or traffic profile. Fig. 1 shows a typical load profile [3] across one week, which clearly exhibits significant spatial and temporal fluctuations. The corollary is that during either low or no traffic periods i.e., early mornings or daytime in residential areas, when loads are small, many BS are underutilized, but still consume significant amounts of energy. Various techniques have been proposed [4]–[9] to reduce energy consumption in network operations by either powering down or putting the BS to sleep during low traffic periods. While such dynamic schemes regulate the energy efficiency by switching the BS on/off depending on network traffic variations, sustaining service provision to those cells which have been switched off raises major design challenges. For example, ensuring regulatory constraints are upheld, protecting spatial coverage, interference management, and the inevitable increasing power consumption to service mobile stations (MS) in off-cells. The approach adopted in [5] and [6] achieves BS energy savings by switching certain macrocells off and then applying cell zooming, so deploying more but smaller cells. A shortcoming of increased cell deployments in a particular area is it can lead

\(^1\)Gartner Inc. Research, 2011.
to a higher handover frequency and occurrences of the ping-pong effect [8] due to greater incidences of BS switching. This incurs higher signalling overheads and ultimately compromises the overall service delivery.

This paper investigates dynamic traffic-aware BS switching modes, where the BS can alter its operating modes between standard BS operations and switching to relay station (RS) mode, the so-called BS-RS Switching model. Depending on the traffic fluctuations, load profiles are divided into two categories; i) Zero-to-medium traffic period - when a BS switches to the RS mode and turns off all its high-power consuming equipment; and ii) Peak traffic period - when all BS are fully active. The rationale for switching from a BS to RS mode is to ensure those MS that would be served by the switched off cell and may suffer deep fading, are still able to receive the same QoS. Furthermore, since the propagation distance has been shortened between the MS and serving BS via the backhaul connection, the required MS transmit power is concomitantly reduced compared with the BS sleep and cell zooming technique [5]-[6].

The remainder of the paper is organized as follows. In Section II, the BS-RS Switching model is formally introduced. In addition, both the propagation loss and power consumption models are considered together with the supporting outage probability theory. Section III provides an analysis of the energy saving simulation results using the proposed energy probability theory. Section IV further provides an analysis. It consists of seven arbitrary hexagonal shaped cells without sectoring. The centre BS is kept switched on all the time, with the other BS having the capability to switch to a relay (RS) mode depending on their traffic conditions. Each BS is located at the centre of a cell and possesses an omnidirectional antenna. Every cell also has an amplify-and-forward RS at the same position with the equal coverage capability as the BS. In this arrangement, both the BS and RS use a common antenna. The user arrival rate for BS$_m$ at time $t$ is modelled as a Poisson process with mean arrival rate $\lambda_m(t)$ [users/sec], under the assumption that the service time $h$ [sec/user] is constant. The traffic profile of BS$_m$ is $\rho_m(t) = \lambda_m(t).h$, which is varied as a function of time over a 24-hour period. Users are randomly located in each cell according to a normal distribution.

The two load profile categories defined above will now be considered in respect of the proposed BS-RS Switching cellular network model:

**Case I: Zero-to-medium traffic period:** During this period, certain BS will be switched off to conserve energy, while low-powered RS are alternatively used to cover the area of switched off cell. BS$_m$ can be switched to RS mode provided neighbouring active BS are able to handle all the MS served by BS$_m$. The approximate handover traffic $\tilde{\rho}(t_{mf})$ of this BS is distributed among the neighbouring active BS according to their own traffic profile, i.e., traffic loads $\rho_1(t_{mf}), \rho_2(t_{mf}), \ldots, \rho_{M_m}(t_{mf})$ are distributed to the $1^{st}$, $2^{nd}$, $\ldots$, $M_m^{th}$ neighbouring active BS, respectively. For simplicity, the handover traffic is assumed to be equally distributed amongst the neighbouring active BS for homogeneous traffic conditions, so the handover traffic of each neighbouring active BS is approximated as:

$$\tilde{\rho}_1(t_{mf}) = \tilde{\rho}_2(t_{mf}) = \ldots = \tilde{\rho}_{M_m}(t_{mf}) = \tilde{\rho}(t_{mf})/M_m$$

The new cell traffic load for each of the neighbouring active BS when BS$_m$ is switched to RS mode at $t_{mf}$ is then:

$$\tilde{\rho}_n(t_{mf}) = \tilde{\rho}(t_{mf}). \left(1 + \frac{1}{M_n}\right); \quad n \in M_m$$  \hspace{1cm} (1)

So when BS$_m$ is switched to RS mode at time $t$, the following two conditions must be satisfied [3]:

$$\tilde{\rho}_n(t) < \rho_{max}; \quad \forall n \in M_m$$  \hspace{1cm} (2)

and

$$\tilde{\rho}_n(t) < \rho_{th}$$  \hspace{1cm} (3)

where $\rho_{max}$ is the maximum traffic load that the neighbouring active BS$_n$ for $n = 1, 2, \ldots, M_m$ is able to handle and $\rho_{th}$ is the switching threshold.

When switching from a RS mode back to the BS mode, the corresponding traffic profile condition to be upheld is:

$$\tilde{\rho}_n(t) \geq \rho_{th}$$  \hspace{1cm} (4)

**Case II: High traffic period:** In this scenario, all BS actively provide services, with some likely to be more crowded than others. While a BS with a low traffic load is able to serve MS in a neighbouring cell which may have a high traffic load, by increasing its transmit power to reduce the blocking probability in the crowded cell [8], this particular situation is not considered in this paper.

A number of benefits ensue from adopting the new BS-RS Switching model compared to the traditional BS sleep approach [5]-[6]. These include:

![Diagram](image-url)
i) minimising the average energy consumption in both the DL (BS) and UL (MS) in the Case I scenario;
ii) maintaining the same coverage and QoS;
iii) Lower outage probability compared with [5] and [6].

B. Propagation Channel Model

This paper uses a modified IEEE 802.16j channel model based on the log-normal shadowing path-loss paradigm with the Type B (LOS/NLOS) intermediate path-loss condition being employed for the links between the BS-MS/RS-MS [10]. All the various system parameters and their values are provided in the TABLE I. It is assumed the path-loss effect with zero mean and a standard deviation $\sigma$ for $i = 1, 2, \ldots, M$. $P_{r,th}$ is the minimum threshold received power to ensure a minimum QoS and $PL(d_i)$ is the propagation path-loss at distance $d_i$ which includes shadowing effects.

D. Outage Probability Analysis

The energy-saving performance of the proposed BS-RS Switching model is analysed under certain outage probability constraints. Outage can occur for two reasons [13]: i) the received signal strength is less than a predefined signal strength threshold, $\gamma$; and/or ii) there is no available service channel. Since the switching operation is only performed during zero-to-medium traffic loads, limited service channel availability is a highly improbable cause of outage in the BS-RS Switching technique. Let $\Psi(d_i)$ denote the outage probability at the $i^{th}$ MS, with a distance $d_i$ between MS and the served BS or RS, and $\gamma = P_{r,th}$. The signal strength outage probability at distance is then:

$$\Psi(d_i) = P_r(P_{r,i} \leq \gamma) = \Phi \left( \frac{10 \log_{10} \left( \frac{\gamma}{P_{r,i}} \right)}{\sigma} \right)$$

where $P_{r,i}$ and $P_{r,th}$ are respectively the transmitted and received signal powers of the $i^{th}$ MS at distance $d_i$, and $\Phi(\cdot)$ is the cumulative distribution function (CDF) of standard normal distribution.

E. Problem Formulation

Given the cell scenario in Fig. 2, it is assumed there are $N$ available channels in every cell for transmission, with each having a different channel gain and bandwidth $W = B/N$, where $B$ is the cell bandwidth. For simplicity, it is also assumed that different frequency bands are used by adjacent BS so ICI can be ignored. If $P_{i,min}$ is the minimum channel transmission power which guarantees a prescribed minimum data rate $r_{min}$ for a user, then it must satisfy the following:

$$r_{min} = W \log_2 \left( 1 + \frac{\eta_0 P_{i,min}}{d^\alpha} \right)$$

so:

$$P_{i,min} = \frac{(2^{r_{min}/W} - 1) d^\alpha}{\eta_0}$$

where $\alpha$ is the path-loss exponent; $\eta_0 = G_0/90$ includes the effect of the antenna gain $G_0$ and thermal noise $N_0$, and $d$ is the distance from the BS to the MS.

Equation (11) reveals the transmit power depends on the distance between the BS and MS, so to achieve a given minimum
data rate, the aim must be to maintain a minimum distance between the transmitter and receiver to reduce propagation attenuation. In the BS-RS Switching model, since the RS is deployed at the same position as the BS, the distance between a BS and MS will be the same when the BS is switched to RS mode, whereas in other models [5]-[9] [12] [13], this distance can be significant.

In addition, the overall cell throughput can be derived from:

$$ R = B \sum_{i=1}^{N} \log_2 \left( 1 + \frac{\eta_i P_{i,t}}{d_i} \right) $$

Based on (12) and the total BS power consumption, the energy efficiency (EE) of a cell in bits per joule [14] is:

$$ \eta_{EE} = \frac{R}{P_T} = \frac{B \sum_{i=1}^{N} \log_2 \left( 1 + \frac{\eta_i P_{i,t}}{d_i} \right)}{a_m P_T + P_f} $$

where $P_T$ and $P_{i,t}$ are the total power consumption in the DL and $i^{th}$ channel transmission power respectively. To attain a high EE while concurrently guaranteeing the QoS for each user, the objective is to turn off certain BS and switch to low-powered RS mode during zero-to-medium traffic periods. BS-RS Switching decisions are based upon whether the traffic load is less than a prescribed threshold within a cell over a particular time interval, so the design problem can thus be accordingly formulated as:

$$ \max_{A_m} \eta_{EE} $$

s.t. \same \Psi(d_i), R and coverage as that when all BS are active,

$$ \sum_{i=1}^{N} P_{i,t} = P_t \leq P_{max}, $$

$$ W \log_2 \left( 1 + \frac{\eta_i P_{i,t}}{d_i} \right) \geq r_{min}, \forall i, $$

and $A_m(x) \in \{0,1\}, \forall x \in \{t, t+1\},$

where $P_t$ and $P_{max}$ are respectively the total and maximum transmission powers of a particular BS. $A_m(t)$ is the mode switching activity function for $BS_m$. BS-RS Switching depends upon the traffic load at time $t$ and this is performed on an hourly basis throughout the day with the satisfaction of eq. (2) & (3), i.e. $\forall \rho(t) < \rho_{th}$ for $t = 1, 2, \ldots, 24$, where $\rho$ is the vector of all traffic loads in each cell during one day, and $\rho_{th}$ is the threshold traffic load required to switch the operation mode (either BS-RS or RS-BS). The objective function in (14) is numerically solved using an exhaustive search algorithm. The minimum energy consumption performance of both the BS-RS Switching model and BS sleep mode technique [5]-[6] will now be investigated.

### III. SIMULATION AND RESULTS ANALYSIS

To assess the energy efficiency performance of the proposed BS-RS Switching model, both the BS and MS perspectives were analysed, in a test environment developed using Matlab. TABLE I details all the simulation environment parameters, which were chosen to be congruent with the 3GPP LTE specifications [15], with hexagonally shaped macrocells considered. The values of $a_{m,BS}$, $a_{m,RS}$, $P_f,BS$ and $P_f,RS$ were respectively preset to 21.45, 7.84, 354.44W and 71.5W, as in [4] and [14]. Hourly time intervals were used in the analysis as in [16], with the traffic arrival process in each interval assumed to be Poisson and users located in each cell according to a normal distribution. For EE measurements, the bandwidth of each cell was 5MHz and the MS bit-rate requirement 90kbps. The various hourly interval results for both BS-RS Switching and the BS sleep [5]-[6] techniques were then averaged and compared across an entire day.

Four hourly snapshots of the energy consumption in each cell during different traffic conditions are shown with cell activation pointers (CAP) in Fig. 3. The CAP ‘1’ nomenclature refers to when the BS is active i.e., $A_m = 1$ for $BS_m$ at time $t$ while the ‘0’ means the corresponding BS is switched to RS mode i.e. $A_m = 0$. The plots clearly reveal the improved energy consumption of each cell compared with no switching. For example, in the 20th hour graph, three BS can be switched off and supported by the RS, while in the situation when all BS are active, i.e., 15th hour, and the CAP are all ‘1’, no energy savings are feasible. To ascertain the energy saved by using the BS-RS Switching paradigm compared with putting the BS to sleep in each cell during the day, Fig. 4 and 5 plot the corresponding average percentage energy savings for the DL and UL respectively. For the former, an overall energy saving of up to 30% has been achieved in different cells depending on the traffic load variations in those cells, while up to 38% average energy saving is achieved for the MS. The additional energy consumed by the RS in the BS-RS Switching model is compensated for by maintaining the same propagation distance
between the BS and MS, via the RS which requires lower transmit powers. In contrast, for the sleep mode technique, the propagation path-losses are higher because of the longer distances between the BS and off-cell MS, so the transmit powers are greater. Note, in both Fig. 4 and 5 there is no saving for the centre cell #1 because it is always active.

To ensure the minimum QoS provision is upheld, the average achievable DL data rate in each cell for the BS-RS Switching and BS sleep modes were analysed across an entire day, with the corresponding results displayed in Fig. 6. In this context, the maximum transmit power was considered, irrespective of the distance between BS and MS. Fig. 6 reveals the proposed BS-RS Switching mode improved the average data rate in each cell, with the exception of centre cell #1, which is kept on all the time in both cases. The graph also confirms the data rates achieved with the new model are the same as those when all BS are active, so there is no compromising of the QoS in securing significantly lower energy consumption.

To evaluate the corresponding signal outage performance in the UL, the CDF of the respective received signal strengths are displayed in Fig. 7, where the signal outage probability threshold $\gamma$ is defined in accordance with the LTE specification [15]. The results confirm that in the proposed BS-RS Switching model, no users will be in the outage region compared to nearly 15% when the BS sleep with cell zooming technique [5] is applied. Fig. 8 shows the EE performance for increasing cell loads for the BS-RS Switching and BS sleep approaches. In the former, the EE improved because all off-cell MS consume the same transmission power. This contrasts with the sleeping
technique which has an approximately constant EE due to the increased power consumption of the off-cell MS offsetting any savings made by putting certain BS to sleep. This is also the reason for the correspondingly superior signal outage performance of the BS-RS Switching model, particularly at high cell loads. This vindicates the rationale of adopting the BS-RS Switching paradigm to achieve noteworthy improvements in EE while concomitantly maintaining the QoS provision.

IV. CONCLUSION

This paper has presented an energy efficient cellular network model, which switches from a base station (BS) to a relay station (RS) mode during zero-to-medium traffic periods. The rationale for the BS-RS Switching model is to guarantee undisrupted communications between the mobile station and BS and thereby ensure the same quality-of-service (QoS) level as would be provided in normal BS mode. The simulation results confirm the proposed BS-RS Switching model reduces energy consumption in both the up and downlinks while sustaining the requisite QoS. In the current simulation scenario, it has been assumed a RS is deployed at the same BS position and has the same coverage. Future work will focus on deploying more RS within a macrocell to keep the BS switched to RS mode for longer periods using dynamic switching, to secure further energy savings. The integration of cell zooming and load balancing strategies during peak macrocell periods will also be investigated.
