ALMA observations of α Centauri

First detection of main-sequence stars at 3 mm wavelength

(Affiliations can be found after the references)

Received 20 October 2014 / Accepted 3 December 2014

ABSTRACT

Context. The precise mechanisms that provide the non-radiative energy for heating the chromosphere and the corona of the Sun and those of other stars constitute an active field of research. By studying stellar chromospheres one aims at identifying the relevant physical processes. Defining the permissible extent of the parameter space can also serve as a template for the Sun-as-a-star. This feedback will probably also help identify stars that potentially host planetary systems that are reminiscent of our own.

Aims. Earlier observations with Herschel and APEX have revealed the temperature minimum of α Cen, but these were unable to spatially resolve the binary into individual components. With the data reported in this Letter, we aim at remedying this shortcoming. Furthermore, these earlier data were limited to the wavelength region between 100 and 870 μm. In the present context, we intend to extend the spectral mapping (SED) to longer wavelengths, where the contrast between stellar photospheric and chromospheric emission becomes increasingly evident.

Methods. The Atacama Large Millimeter/submillimeter Array (ALMA) is particularly suited to point sources, such as unresolved stars. ALMA provides the means to achieve our objectives with both its high sensitivity of the collecting area for the detection of weak signals and the high spatial resolving power of its adaptable interferometer for imaging close multiple stars.

Results. This is the first detection of main-sequence stars at a wavelength of 3 mm. Furthermore, the individual components of the binary α Cen AB are clearly detected and spatially well resolved at all ALMA wavelengths. The high signal-to-noise ratios of these data permit accurate determination of their relative flux ratios, i.e., $S^B/S^A = 0.54 \pm 0.04$ at 440 μm, $0.46 \pm 0.01$ at 870 μm, and $0.47 \pm 0.006$ at 3.1 mm, respectively.

Conclusions. The previously obtained flux ratio of 0.44 ± 0.18, which was based on measurements in the optical and at 70 μm, is consistent with the present ALMA results, albeit with a large error bar. The observed 3.1 mm emission greatly exceeds what is predicted from the stellar photospheres, and undoubtedly arises predominantly as free-free emission in the ionized chromospheric plasmas of both stars. The distinct difference in their cyclic activity, the similarity of their submm SEDs appears surprising.

Key words. stars: chromospheres – stars: solar-type – stars: individual: α Centauri AB – submillimeter: stars – radio continuum: stars – binaries: general

1. Introduction

About two thirds of the 133 FGK stars observed at wavelengths of 100 μm and 160 μm by Herschel as part of the DUNES program have suggested that temperature minima are present in their atmospheres (Eiroa et al. 2013). These stars are commonly recognized as solar-type and the chromospheres and coronae were expected on the basis of their known CaII H & K indices and X-ray luminosities.

In the particular case of the nearby binary α Cen A B (G2 V and K1 V), the far-infrared (FIR) spectral evidence for the phenomenon of a temperature minimum was quite convincing, although the pair was spatially unresolved by our long-wavelength observations (Liseau et al. 2013; Wiegert et al. 2014). Furthermore, since adequate theoretical stellar model atmospheres longward of 40 μm were lacking, relative flux ratios had to be deduced by extrapolation from data obtained at shorter wavelengths. This could potentially lead to large errors, since α Cen B is known to be considerably more active than the primary α Cen A (Ayres 2014), and one might therefore a priori not expect the scaling in the optical (photospheric flux) to also apply to the FIR/submm regimes, where the radiation originates at higher atmospheric levels in the chromosphere. There, the continuum opacity is controlled by free-free H− processes and temperatures in these optically thick layers, which follows the photospheric (negative) temperature gradient and samples the temperature inversion in the lower chromosphere (temperature minimum). Thereafter, temperatures start to increase again.

The Herschel photometry permitted the rough spectral coverage of the temperature minimum up to about 500 μm, where the measurements at the longest wavelengths were at the very limit of the detection capability of the SPIRE instrument (Griffin et al. 2010). In addition, the spatial resolution of the 3.5 m Herschel single-dish telescope (Pilbratt et al. 2010) was inadequate for resolving the binary into its components. Both of these shortcomings could be mitigated using the Atacama Large Millimeter/submillimeter Array (ALMA) is particularly suited to point sources, such as unresolved stars. ALMA provides the means to achieve our objectives with both its high sensitivity of the collecting area for the detection of weak signals and the high spatial resolving power of its adaptable interferometer for imaging close multiple stars. The previously obtained flux ratio of 0.44 ± 0.18, which was based on measurements in the optical and at 70 μm, is consistent with the present ALMA results, albeit with a large error bar. The observed 3.1 mm emission greatly exceeds what is predicted from the stellar photospheres, and undoubtedly arises predominantly as free-free emission in the ionized chromospheric plasmas of both stars. The distinct difference in their cyclic activity, the similarity of their submm SEDs appears surprising.
limer/submillimeter Array (ALMA), and in this Letter we report our initial results of these observations. The ALMA observations and data reduction are described in Sect. 2, the results are presented in Sect. 3, and their relevance discussed in Sect. 4. Finally, Sect. 5 briefly lists our main conclusions.

2. Observations and data reduction

The binary α Cen A+B was observed in three ALMA continuum bands, with 7.5 GHz effective bandwidth spread over four spectral windows in each of the bands. The observations in Band 3, centered on 97.5 GHz (3.1 mm), were taken on 2014 July 3, and they used 30 antennas and a total observing time of ~50 min, of which ~30 min were spent on-source. The Band 7 observations, centered on 343.5 GHz (872.8 µm), were taken on 2014 July 7 using 32 antennas with ~20 min of observing time with ~2 min on-source. Finally, the observations in Band 9, centered on 679 GHz (441.5 µm), were taken on 2014 July 18 using 31 antennas and ~30 min total and ~8 min on-source observing time.

Calibration was performed using the CASA package[2] following standard procedures and using, for all data sets, the quasar J1617–5848 as complex gain calibrator, which was within 12′ of α Cen. The quasar J1427–4206, at 18:5 separation, served as bandpass calibrator. The secondary gain calibrator J1508–4953 was observed in Band 9.

Flux calibration was done using Ceres in Bands 3 (97.5 GHz, 3075 µm) and 9 (679 GHz, 441.5 µm), when at 57′′ elevation, while α Cen was at 50′′. Titan was used for Band 7 (343.5 GHz, 872.8 µm), when it was at 59′′ elevation and α Cen at 43′′. Bootstrapping the fluxes of our calibrators yielded a flux for J1617–5848 of 1.555 ± 0.002 Jy (Band 3), 0.520 ± 0.001 Jy (Band 7), and 0.321 ± 0.003 Jy (Band 9). For J1427–4206, we found 2.434 ± 0.004 Jy and 1.498 ± 0.005 Jy in Bands 7 and 9, respectively, and for the secondary gain calibrator J1508–4953 in Band 9, we found 0.71 ± 0.03 Jy. Based on the flux values for the calibrators that are provided by the observatory, we estimate the absolute flux calibration to be accurate to within 5%, 7%, and 15% for Bands 3, 7, and 9, respectively. These calibration data are updated on a regular basis, within at most three weeks, and no flux variations for the calibration sources that exceeded the quoted errors were noticed.

Finally, imaging was performed using Briggs weighting in Band 7 and natural weighting on Bands 3 and 9. In Band 9, α Cen A was strong enough to perform self-calibration, improving the rms noise. In the final, primary beam-corrected images, the rms noise per synthesized beam in the pointing center was 0.02 mJy beam⁻¹ (1″72 × 1″50, at PA = 19°) in Band 3 (3.1 mm), 0.2 mJy beam⁻¹ (0″42 × 0″28, 47′) in Band 7 (872.8 µm), and 1.0 mJy beam⁻¹ (0″22 × 0″16, 35′) in Band 9 (441.5 µm). Because an error in the pointing position meant that the binary was offset from the pointing center, the rms toward α Cen B is somewhat increased as is noticeable in Table[1].

3 Results

In all bands the binary was clearly detected at high signal-to-noise ratio (S/N) and was well resolved into its individual components. An example is shown in Fig.[1] for the ALMA observation at 872.8 µm (343.5 GHz, Band 7). The measured flux densities are reported in Table[1] and also displayed graphically in Fig.[2].

4 Discussion

In the Rayleigh-Jeans regime (RJ), optically thick free-free emission (or Bremsstrahlung) will behave as $S_{\nu} \propto \nu^{2}$, so that the spectral index, $\alpha = \Delta \log S_{\nu}/\Delta \log \nu = 2$. For optically thin emission, $\alpha_{\nu}$ is distinctly different and slightly negative, i.e., essentially zero (see, e.g., Wright & Barlow 1975). In Fig.[2] we present the flux densities $S_{\nu}$ of α Cen A+B that were measured

\[ S_{\nu} = \frac{2nk_{B}c^{3}}{4\pi} \left[ \ln \left( \frac{\nu^{2} \sigma_{T} M_{\odot}}{D^{2} c^{3} \nu^{2} S_{\nu}} + 1 \right) \right]^{-1} \]

(see, e.g., Liseau et al. 2013).

with ALMA at three frequencies, and in Table 1 we also present the observed values of α. In the figure, the dashes connecting the data points are meant to guide the eye and can be compared to the dotted line that shows the spectral shape of optically thick free-free emission. Deviations may be introduced by different depth views at different frequencies along the temperature gradient (down to τν ~ 1), since the dependence of Sν on T is linear in the optically thick RJ-regime. The measurements seem to indicate changing opacities. However, a more conclusive statement would require a tighter spectral sampling, including the intermediate ALMA bands.

One can use observations on either side of the turnover frequency ν1, i.e., where the free-free spectrum turns from optically thick to thin, to construct an empirical model chromosphere. For α Cen A and B, empirical chromosphere models based on optical line data (Ca II K) have been presented by Ayres et al. (1976), with chromospheric temperatures not exceeding 5700 K.

In the optically thick case, the measured brightness temperature, T_B, corresponds to the actual temperature of the emitting gas, and once the temperature is known, the density can be derived from the optically thick observations, since Sν ∝ EM × T^−1/2, and where EM = ∫n_e n_i dh is the emission measure. In the Sun, the height of the chromosphere ∫dh corresponds to about 0.1% of its radius. It is reasonable to assume that this will not be very different in the α Cen stars. Models of the chromospheres of these stars will be presented in a forthcoming paper.

To obtain data in the optically thin regime would require observations of the stars at longer wavelengths (lower frequencies). However, to the best of our knowledge, such data are not available for α Cen A and B. Observations of this kind have, however, recently been reported for three other solar-type main-sequence stars by Villadsen et al. (2014). That demonstrates that this type of observation has now become feasible with large telescope arrays operating at microwave wavelengths, and they should also be attempted for the α Centauri binary. With declinations south of ~60°, the Australia Telescope Compact Array (ATCA) could be an option.

Observations and/or models of the quiet Sun have been published by, for example, Vernazza et al. (1981), Loukitcheva et al. (2004), Fontenla et al. (2007), Avrett & Loeser (2008), and De la Luz et al. (2014). Evidence is, however, mounting that the heating of the solar chromosphere and corona is dominated by active, magnetically controlled, processes (Carlsson & Stein 2004; Fontenla et al. 2007; Avrett & Loeser 2008), and it remains to be seen what quiet stellar chromosphere models could add to the more complete understanding of the physics of the Sun and other stars. However, the Sun is considered to be a relatively inactive star and in this context, it could also be interesting to note that the α Cen stars show very different levels of activity, with α Cen A being much quieter even than the Sun, whereas α Cen B is considerably more active (e.g., Ayres 2014). The great similarity in their submm SEDs is therefore quite astounding. Finding the solution to this enigma may also provide valuable feedback for understanding the Sun-as-a-star.

5. Conclusions

The nearby solar-type star α Cen has been clearly detected by ALMA at three wavelengths between 0.4 to 3.1 millimeters. In particular, the spectacular detection of both stars at 3.1 mm is the first ever of its kind. Also, these observations conform to our earlier data, which was obtained by the DUNES team with Herschel, and confirm the existence of the temperature minima in the atmospheres of the binary components α Cen A and B.

Below, we briefly summarize our main conclusions:

- At FIR/submm wavelengths, the binary was not spatially resolved by the Herschel Telescope; however, the 4″ binary separation in 2014 is easily resolved by the present ALMA observations.
- The new ALMA data have provided accurate flux ratios that agree with our previously estimated value.
- The measured spectral indices are consistent with emission that is dominated by optically thick free-free processes (Bremsstrahlung).

4 For the stellar radii, we use the data compiled in Table 4 of Wiegert et al. (2014), i.e. R_A = 1.224 ± 0.003 R_⊙ and R_B = 0.863 ± 0.003 R_⊙.

L4, page 3 of 4
The long-wave emission (ALMA-Band 3 at 97.5 GHz) is undoubtedly of chromospheric origin, and originates in material at temperatures in excess of 8000 K.

The chromospheres of the α Cen stars seem similar in appearance to empirical models of the quiet Sun. However, the ALMA data hint at the possibility that the less active primary α Cen A, and the more active companion B, both heat their chromospheres to higher temperatures.

Acknowledgements. We thank the referee for a thoughtful and detailed report. Thanks also go to the members of the Nordic ARC node (http://www.nordic-alma.se/), and we wish to thank the ALMA staff for their assistance with the observations. This paper makes use of the following ALMA data: ADS/JAO.ALMA#2013.1.00170.S. ALMA is a partnership of ESO (representing its member states), NSF (USA), and NINS (Japan), together with NRC (Canada) and NSC and ASIAA (Taiwan), in cooperation with the Republic of Chile. The Joint ALMA Observatory is operated by ESO, AUI/NRAO, and NAOJ.
