Introduction
The technique of data assimilation is employed in a novel way for a planetary atmosphere to perform a complete spatial and temporal simulation of martian atmospheric constituent data over periods of several Mars years. Observations of martian atmospheric constituents, generally made from orbiting spacecraft, are often sparse and incomplete. A global circulation model can be used to predict the transport, phase changes, and chemical reactions that these species undergo. If constrained by observations, it can then provide a consistent interolation to unobserved regions and, in principle, a useful a priori for future retrievals. Furthermore, any consistent misfit between the model predictions and new observations can be used to identify potentially important physical processes that are missing from the model, including inferring the presence and location of sources and sinks.

Data Assimilation
Data assimilation is the combination of observations and models, which provide physical constraints and propagate the observational information that is introduced. This offers some significant potential advantages for the analysis of atmospheric data from other planets [4]. Thermal and dust opacity observations have been successfully assimilated over a period of about eight Mars Years (MY), including data from the Thermal Emission Spectrometer (TES) aboard NASA Mars Global Surveyor ([5, 6]) in MY24–27 and Mars Climate Strokeman (MCS) from NASA Mars Reconnaissance Orbiter (MRO) in MY28–31.

Previous work has focused on assimilation of temperature and total column dust opacity into a Mars global circulation model (MGCM), which includes the option of a coupled photochemical model [2, 3]. We now add assimilation of water vapour, water cloud aerosol and chemical species. Results shown in this paper for water vapour are for MY24–25 and for water ice and ozone are for MY30.

Below: dust absorption optical depth at 9.3 μm, normalised to 810 Pa and averaged over longitude. This should be multiplied by about 2.6 to get a broadband visible dust total extinction. The data here are from [7]. assimilation gives similar zonally- and diurnally-averaged results.

Ozone Assimilation
The Mars Color Imager (MARCI) [1] aboard MRO provides near-daily global mapping of ozone column concentration. These data were used along with MGS temperature and dust opacity observations, which help to ensure a realistic atmospheric dynamical state. Ozone has been successfully assimilated into the MGCM and can be shown to improve the model’s predictable capacity, although the system generally retains information from observations over only a short period of time, consistent with previous studies with various photochemical models. Ozone assimilation is a major advantage in the current simulation because it is able to highlight differences in the structure of the martian polar vortex when compared to a control model run.

Water Vapour Assimilation
The MGCM can include a full water cycle, coupled to the model radiation scheme. Retrievals of water vapour column data from TES [5] were assimilated into the model [9], including the global water vapour column error in the MGCM to around 2–4 ppb depending on season.

Below: zonal-mean water vapour mass mixing ratios for the equator, the two polar hemispheres, and the mid-latitudes, (and (d) winter seasons. Black contours show the mean gravitational circulation (50 km) with solid, dashed lines representing clockwise and anticlockwise patterns. Dotted white lines show ice mass mixing ratios. Water transport by transient eddies is largest at northern mid-latitudes close to equinox, with a net northward transport of water vapour toward the ice cap. (b) model with subliming ice deposits around the main ice cap, and (c) a model with only the main ice cap represented, revealing the impact of subliming ice deposits around the north polar ice cap (located between 75°–80° N and 120°–210° E).

Water Ice Assimilation
We have assimilated MCS opacity data which includes vertical profile information [10]. This can be challenging since the MGCM rapidly converts between water vapour and ice.

Right: zonal-mean water ice opacity fields from the assimilation procedure around northern hemispheres summer solstice and autumn equinoxes of MY30.

Below: zonal-mean temperature and cloud field around northern hemispheres mid-latitudes. (a) summer, (b) autumn, and (c) winter, and for local times of 3 am (–4) and 3 pm (–4). Black contours show the assimilated ice opacity. Tropical clouds result in additional local heating during the day and cooling at night. Heating from tropical atmospheric temperatures increase to 10–15 K around 20 km altitude. Polar cloud ice, which are less optically dense, have a smaller radiative impact. Clouds also have an indirect impact on the atmosphere by strengthening the overlying circulation, leading to an increase in temperatures over the poles by around 6–8 K at 50–60 km altitude, and transporting additional radiative heating, leading to temperature increase in the tropics of around 2 K.

Conclusions
The data set resulting from a constituent assimilation allows a detailed study of the atmospheric state that is not possible using observations or models alone. The MGCM has the ability to transport many independent tracers, so a wide range of photochemically active and passive trace species can be assimilated simultaneously as observations become available.

Chemical data assimilation is a relatively new area of Mars research. Assimilation of even a single chemical species can provide constraints on other observed constituents and provide estimates for unobserved constituents. Chemical rate coefficients, primarily from laboratory experiments, can be tested by reconciling observational datasets and theoretical models. The assimilation of such observations should lead to improved in martian chemical models and better use of present and future observations, such as those from 2016 ESA ExoMars Trace Gas Orbiter.
