C. elegans commonly encounters many environmental hazards including pathogenic bacteria. In order to respond appropriately, the worm must integrate multiple environmental cues including food availability and pathogenicity to maximize its chances of survival. What are the molecular mechanisms that allow this finely tuned integration of information from both the nervous and immune systems? Previous work has shown that neuronal signaling can profoundly affect susceptibility to infection by mediating pathogen avoidance.1,2 Mutations in the neuronally expressed G protein coupled receptor (GPCR) npr-1 gene, which encodes a homolog of the neuropeptide Y receptor, can mediate the behavioral immune response of avoidance of a number of pathogens including Pseudomonas aeruginosa.3 In comparison, our recent work has shown that during M. nematophilum infection, signaling via the neurotransmitter serotonin can suppress the cellular immune response in the rectal epithelium (Fig. 1A).1

How does neuronal signaling influence the immune response? The amphid chemosensory neuron pair ADF, which are exposed to the external environment, have the ability to modulate behavioral and cellular immune responses to Pseudomonas aeruginosa and M. nematophilum.1,2 These responses rely on the regulation of the biosynthetic enzyme tryptophan hydroxylase-1 (tph-1) in ADF neurons. TPH-1 is the rate-limiting enzyme in the synthesis of serotonin, and animals carrying a putative null allele for this gene are deficient for serotonin production and signaling.4 Transcription of tph-1 in ADF is regulated by a number of conditions including food quality, availability and heat stress.2,5,7

Our work shows that the cellular immune response to M. nematophilum is negatively regulated by tph-1 expression in ADF neurons and that this acts via the serotonin receptors SER-1 and SER-7 to regulate signaling by the G-protein goa-1 (Gto) in the rectal epithelium (Fig. 1A).1 M. nematophilum innately repels C. elegans and this behavioral immune response is not affected by mutations in tph-1.1,8 Using a transcriptional reporter we found that exposure to this pathogen does not increase tph-1 expression in ADF.1
Pseudomonas ingestion increases intracellular calcium, which then increases tph-1 transcription and the levels of serotonin in ADF. This response is cell-autonomously regulated by the C. elegans homolog of calcium/calmodulin-dependent protein kinase II (CaMKII), UNC-43. This suggests that the same gene in the same chemosensory neurons can show differential regulation in response to different pathogens. In this case, Pseudomonas ingestion increases intracellular calcium, which then increases tph-1 transcription and the levels of serotonin in ADF. This response is cell-autonomously regulated by the C. elegans homolog of calcium/calmodulin-dependent protein kinase II (CaMKII), UNC-43. This suggests that the same gene in the same chemosensory neurons can show differential regulation in response to different pathogens.
Dense Core Vesicle Release and the Immune Response

Unlike small synaptic vesicles, which are localized to synaptic zones, dense core vesicles (DCVs) are diffusely scattered throughout the nerve terminal. DCVs release a number of bioactive molecules including serotonin, and neuropeptides, many of which influence the immune response. Reducing DCV release in *Pseudomonas aeruginosa* infections, suggesting that a vator protein required for DCV secretion (the calcium activator protein required for DCV secretion) results in increased resistance to *Pseudomonas aeruginosa* infections, suggesting that molecules released from DCV’s suppress this immune response. Different DCV cargoes are required to modulate the response to different pathogen infections. Our work has shown that exogenous serotonin suppresses the rectal epithelial immune response to infection with *M. nematophilum*, while reductions in serotonin synthesis results in an increased immune response. In comparison, during *Pseudomonas aeruginosa* infections, loss of serotonin has no effect on cellular immunity, while mutations in the neuropeptide processing enzymes *egl-3* and *egl-21* result in enhanced pathogen resistance. This is due to the action of the insulin-like neuropeptide INS-7, acting as a DAF-2 agonist to negatively regulate resistance to *Pseudomonas* infection (Fig. 1C).

Further DCV cargoes have also been implicated in modulating the immune response. Zugasti et al. have demonstrated that TGF-β signaling from the nervous system promotes expression of Caenacipeptides in the epidermis following infection with the fungal pathogen *Drechmaria coniospora* (Fig. 1C). Recent work by the Abhallay lab has shown that during *Pseudomonas* infection OCTR-1, a putative catecholamine receptor whose ligand octopamine, is the invertebrate equivalent of noradrenaline, is required in ASH and ASI neurons to negatively regulate the p38 MAPK and unfolded protein response in pharyngeal and intestinal cells (Fig. 1B). However, whether octopamine acts as the OCTR-1 ligand to mediate this effect on the immune response is currently unclear. Another monoamine neurotransmitter found in DCVs is dopamine. Although direct evidence that this neurotransmitter can modulate the immune response is lacking, dopaminergic neurons have been shown to play a role in enabling the conditioning of *C. elegans* to enteropathogenic *E. coli* so that they are more resistant to infection upon a second exposure (Fig. 1C).

Although there is strong evidence that molecules released from DCVs modulate the cellular immune response, the question of whether neurotransmitter release from small synaptic vesicles can also affect innate immune function remains to be addressed. The availability of *C. elegans* mutants in enzymes required to synthesize these neurotransmitters provides an excellent starting point to address this question.

Neuronal Signaling to Immune Cells; A Direct or Indirect Action?

One key question is how signals originating in neurons in the head are transmitted to distant targets such as the rectal epithelium or intestine. During *M. nematophilum* infection serotonin synthesized and released from ADF chemosensory neurons in the head acts via GOA-1 to modulate the response of rectal epithelial cells in the tail. Although ADF forms synapses with 17 interneurons and sensory neurons, as well as forming gap junctions with 2 additional sensory neurons (www.wormweb.org), the rectal epithelium is not reported to be a direct postsynaptic target. Changes in neuronal connectivity in response to *M. nematophilum* infection are possible, but our observations using a *tpg-1* transpositional reporter suggest this not the case (unpublished data). Serotonin can act at sites microns away from its site of release to activate receptors, however whether it is possible that it could traverse the length of the worm at a high enough concentration to activate receptors in the rectal epithelium is unclear. An alternative explanation is that serotonin could mediate its actions on the rectal epithelium indirectly. This is not a new concept, indeed GOA-1 expressed on cholinergic motor neurons in the ventral nerve cord is known to act downstream of serotonin signaling in the regulation of locomotion.

However, until recently it was not known whether serotonin signaled directly by binding to serotonin receptors expressed on these cholinergic neurons or indirectly by modulating the activity of interneurons, which subsequently activate GOA-1. Recent work by Gürel et al. revealed that the serotonin receptors controlling locomotion, MOD-1 and SER-4 are not expressed in cholinergic motor neurons, but are expressed in non-overlapping sets of interneurons in the head and tail. MOD-1 is also expressed in GABAergic motor neurons in the ventral nerve cord, suggesting that serotonin does indeed act indirectly on GOA-1 in cholinergic motor neurons. Similarly, serotonin may act indirectly on GOA-1 to modulate the immune response in the rectal epithelium. Our worked defined at least SER-1 and SER-7 receptors as playing a role in modulating the epithelial immune response. However, in the absence of infection, the reported expression for SER-1 and SER-7 places neither receptor in the rectal epithelium, suggesting that their action on the epithelium is likely to be indirect.

A Conserved Network of G Proteins Mediate Neurotransmission and Epithelial Immunity

Locomotion in *C. elegans* is dependent upon a network of G-proteins, including EGL-30(Gαq) and GOA-1(Gαo) which act antagonistically in cholinergic motor neurons to regulate acetylcholine release. Loss of *egl-30* results in reduced acetylcholine release and locomotion. Animals lacking *goa-1* show increased release and movement, as well as being resistant to the enhanced slowing on food response mediated by serotonin, suggesting this response is mediated by *goa-1*. Genetic data suggests that GOA-1 acts parallel to or upstream of *EGL-30* in locomotion. In 2012, we showed that the immune response to *M. nematophilum* in the rectal epithelium requires the *EGL-30* (Gαq)-UNC-73(TRIO)-RHO-1(Rhoa)
signaling pathway. Our most recent work shows that GOA-1 signaling acts antagonistically to this signaling pathway in the rectal epithelium, acting upstream of, or in parallel to, EGL-30. This demonstrates that the same conserved G-proteins can mediate different responses in different tissues.

**Neuro-Immune Signaling in Mammalian Systems**

The concept of neuro-immune communication is not restricted to *C. elegans*. Humans undergoing psychological stress show changes in immune measures and are known to become more susceptible to new infections or reactivation of a latent infection. Clinical depression is associated with changes in immune measures and natural killer (NK) cell activity. In mammals both the innate and adaptive immune systems show interactions with the nervous system. Mammalian immune cells express receptors for neurotransmitters, including serotonin, and can be influenced by neuronal signaling. Serotonin is released in response to injury and pro-inflammatory signals and many immune cells express receptors for serotonin including dendritic cells, mast cells and macrophages. Treating T-cells with exogenous serotonin can inhibit proliferation and promote T-cell activation. Serotonin can also act induce mast cell migration and proliferation of NK cells. Dopamine is also implicated in mediating immune responses in mammals. Induction of dopamine release has been shown to suppress systemic inflammation and improve survival in a mouse model of sepsis.

Evidence is also accumulating that this communication is bidirectional and that the immune system can also modulate neuronal signaling. In response to infection, mammalian immune cells can produce neuropeptides, cytokines and neurotransmitters that influence the nervous system and can lead to the development of sickness syndrome and depression. This bidirectional communication means that dysfunction in the nervous system can have a significant impact on the immune system and vice versa. Indeed analysis of people with the autoimmune condition rheumatoid arthritis reveals an increased incidence of depression.

The role of the immune response in regulating neuronal function is yet to be explored in *C. elegans*, however detailed characterization of the neuronal circuits underlying behavior, coupled with our growing understanding of *C. elegans* immunity, provides an excellent starting point for this work.

**Future Perspectives**

Our recent publication together with previous data highlights the profound interrelationship between the nervous and immune systems required for optimal survival. Balancing the inputs of the 2 systems is complex. For example, when food is scarce expending resources mounting an immune response may not always be the most appropriate response. Likewise, mutants defective in DVC secretion are better at combating an opportunistic *Pseudomonas* infection, but this is often accompanied by defects in locomotion that would likely prove detrimental to survival in their natural environment. As classical neurotransmitters become recognized as immunomodulators, it will be interesting to determine whether synaptic vesicle release can also influence the immune response or if this is restricted to DCVs.

Broadening our understanding of the dialog between the nervous and immune systems has the opportunity to provide new treatments options for those developing mood disorders post-infection, or reducing susceptibility to infection for those experiencing psychological stress. The complexity of the mammalian nervous and immune systems mean that dissecting out the signaling pathways important in integrating these systems is extremely difficult. This is why, since a near complete connectome for the nervous system of *C. elegans* exists, the simple worm is likely to continue to play a significant role in understanding the complex interplay between the nervous and immune systems in the future.
