Introduction: Dark inclusions (DIs) are lithic fragments that form a volumetrically small, but important, component in carbonaceous chondrites [1,2]. Carbonaceous clasts similar to DIs are also found in some ordinary chondrites and HEDs [3,4]. DIs are of particular interest because they provide a record of nebular and planetary processes distinct from that of their host meteorite [1,5]. DIs may be representative of the material that delivered water and other volatiles to early Earth as a late veneer [6]. Here we focus on the oxygen isotopic composition of DIs in a variety of settings with the aim of understanding their formational history and relationship to the enclosing host meteorite.

Materials and methods: DIs and related materials were obtained from the following meteorites: CV3s (Allende, NWA 2140, NWA 2364): Samples from Allende cover all categories of the four-fold classification scheme [2] (inclusion numbers analyzed in brackets). Type A clasts (1a1, 4b1, 25s1-TW1) contain chondrules, inclusions and matrix, but are somewhat finer grained than normal Allende material. Type A/B clasts (MZB) are transitional between Types A and B (Fig. 1). Type B clasts (12b1) contain opaque matrix and olivine-rich aggregates and may have experienced a hydration-dehydration cycle [2]. Type C clasts (5a1, ekpb4b1, MZ15, USNM 3876) consist of fine-grained, opaque material similar to Allende matrix. Full descriptions of of the Allende DI samples are given in [2]. DI material from NWA 2140 analyzed for this study is Type A/B and Type A for NWA 2364. HEDs: (Bholghati, PRA 04401, SCO 06040). DIs from the howardite Bholghati have not been analyzed by us for oxygen isotopes. Instead a sequence of 5-10 mg representative whole rock samples have been run to assess its carbonaceous chondrite content. PRA 04401 is an extremely coarse-grained howardite containing a high concentration (~40-50% in places) of nearly cm-sized angular carbonaceous clasts that texturally resemble CM2 material [7]. SCO 06040 is also a coarse-grained howardite breccia, containing a lower amount (~10%) of rounded, up to 2mm diameter, CM2-like clasts [7]. OCs: Sharps (H3.4) is a fragmental breccia containing accessory carbonaceous clasts up to 1cm in diameter [8].

Oxygen isotope analysis was performed by infrared laser-assisted fluorination [9]. All analyses were obtained on untreated whole rock samples (0.5-2 mg). System precision, as determined on an internal obsidi-
... have $\Delta^{17}\text{O}$ values that vary from -0.265 to -0.489‰, consistent with bulk carbonaceous chondrite (CM2) contents of between about 1 and 10%.

Fig. 2 Oxygen isotopic composition of Dark Inclusions. The blue dashed line is the best fit line through the Allende DIs only. Bulk Allende [10]. TFL = Terrestrial Fractionation Line, CRML = CR Mixing Line [11]. CCAM = Carbonaceous Chondrite Anhydrous Mineral line [12]. CM2 field (blue shading) [12], CV-CK field (grey shading) [10].

DIs analyzed in Sharps are clearly distinct from those in either the CV3s or howardites and plot on the CR Mixing Line [11]. The composition of these DIs is not well understood, although they do not appear to be mineralogically related to CR chondrites [8].

Discussion: Mineralogical studies of DIs have played a crucial role in highlighting the importance of parent body processes in modifying the composition of CV chondrites [2, 13]. In particular, DI studies have shown that CV3s, previously regarded as pristine nebular condensates, underwent extensive aqueous alteration [2, 13]. Furthermore, textural evidence indicates that, following aqueous alteration, some DIs experienced a phase of thermal metamorphism, resulting in phyllosilicate dehydration and the formation of secondary Fe-rich olivine (Type B inclusions) [13]. This model was later extended to explain the origin of CV3 Fe-rich matrix olivines in general [14].

The results of previous oxygen isotope studies of DIs have also pointed to the role of aqueous alteration in modifying their primary compositions [1]. As shown in this study, DIs define linear arrays with a shallower slope than the CCAM and with less altered material plotting at the $^{18}\text{O}$-rich end (Type As) and more altered material (Type Bs) at the $^{16}\text{O}$-poor end [1]. However, with respect to phyllosilicate dehydration and secondary Fe-rich olivine formation, oxygen isotope evidence appears less clear-cut [15]. Experimental evidence indicates that dehydration will result in heavy-isotope enrichments, which for Allende matrix olivines are not seen, if the CCAM line is used as a reference [15].

However, DIs in Allende may point to a possible weakness in this argument. In Fig. 2 and 3 DIs do not sit on the CCAM line, but instead define a line of lower slope (Fig. 2). In a similar way, chondrules in Allende plot on a discrete line with a steeper slope than the CCAM line. Analysis of 22 Allende chondrules (OU unpublished data) yield an array with a slope of: $y = -3.45 + 0.97x$ (Fig. 3). If this reference line, rather than the CCAM, is used positive shifts of 7‰ along a mass fractionation line to the array defined by Vigarano DIs is feasible (Fig. 3). This is greater than required by earlier experiments [15]. More recent work has shown that shifts of 7‰ are produced during dehydration of serpentine [16]. Thus, phyllosilicate dehydration, leading to the formation of CV3 Fe-rich matrix olivines, may be a viable mechanism, provided the relevant reference line is steeper than the CCAM [17].
