ABSTRACT

We present source counts at 6.7 and 15 μm from our maps of the Hubble Deep Field (HDF) region, reaching 38.6 μJy at 6.7 μm and 255 μJy at 15 μm. These are the first ever extragalactic number counts to be presented at 6.7 μm, and are three decades fainter than IRAS at 12 μm. Both source counts and a P(D) analysis suggest that we have reached the Infrared Space Observatory (ISO) confusion limit at 15 μm: this will have important implications for future space missions. These data provide an excellent reference point for other ongoing ISO surveys. A no-evolution model at 15 μm is ruled out at >3σ, while two models which fit the steep IRAS 60-μm counts are acceptable. This provides important confirmation of the strong evolution seen in IRAS surveys. One of these models can then be ruled out from the 6.7-μm data.

Key words: surveys – galaxies: evolution – galaxies: formation – galaxies: Seyfert – galaxies: starburst – infrared: galaxies.

1 INTRODUCTION

IRAS galaxy surveys at 60 μm have consistently provided good evidence for a population of star-forming galaxies evolving with a strength comparable to that of active galactic nuclei. This has been confirmed by numerous studies of count distributions and redshift surveys from 0.6 Jy to 50 mJy (Hacking & Houck 1987; Saunders et al. 1990; Lonsdale, Hacking & Conrow 1990; Oliver et al. 1995; Gregorich et al. 1995; Bertin, Dennefeld & Moshir 1997).

This evolving population discovered by IRAS could have very important implications for cosmological studies. In particular, these objects are likely to contribute strongly to the star formation history of the Universe. [Other incidental issues include the possibly significant impact that such objects could have on the cosmological far-infrared background: see e.g. Oliver, Rowan-Robinson & Sanders (1992) and Franceschini et al. (1991).] The populations seen by IRAS are mostly relatively low-redshift (z < 0.2); deeper Infrared Space Observatory (ISO) surveys such as this provide a longer baseline in redshift, giving a better handle on the nature of the evolution.

This paper will discuss the source counts from our maps of the Hubble Deep Field (HDF: Williams et al. 1996).
observations have been described by Serjeant et al. (1997, Paper I), and the source extraction described by Goldschmidt et al. (1997, Paper II): a total of 27 sources were found at 6.7 \( \mu m \), and 22 at 15 \( \mu m \). Further papers discuss the associations with optical galaxies (Mann et al. 1997, hereafter Paper IV) and the models for spectral energy distributions and the star formation history (Rowan-Robinson et al. 1997, hereafter Paper V).

2 OBSERVED SOURCE COUNTS AT 6.7 AND 15 \( \mu m \)

In Paper II we detected seven sources in our 6.7-\( \mu m \) maps and 19 in our 15-\( \mu m \) maps using a well-defined source detection algorithm. To convert these source lists into source counts requires an estimate of the area within which a source of observed flux (\( S_m \)) could have been detected.

To estimate this we need to know the minimum flux (\( S_{\text{min}} \)) detectable at any position. The source detection algorithm requires \( m \) pixels to have intensity \( I(x,y) > T(x,y) \), where \( T(x,y) \) is the threshold intensity. The flux of resulting detections is estimated using an estimated local background intensity \( B(x,y) \). Assuming a well-determined point spread function (PSF), \( P(x-x_0, y-y_0) \), this algorithm gives us a detection limit

\[
S_{\text{lim}}(x_0, y_0) = \text{max}_m \left[ \frac{T(x, y) - B(x, y)}{P(x-x_0, y-y_0)} \right],
\]

where \( \text{max}_m \) is a function giving the \( m \)th largest value. \( T \) is defined for various areas in Paper II and \( B \) is determined by running the sky annulus across the full image.

The PSF is the only uncertainty in this estimate of the survey areas, and we thus decided to investigate this in some detail. One estimate for \( P \) comes from the standard ESA products. The PSF is estimated at 3 \( \times \) 3 sub-pixel positions for each filter and lens position. We drizzled these images together to produce a single PSF for each of our two observing modes. For both bands, the ESA PSF contains a large amount of flux in the wings. These wings may be caused by scattered light or other data reduction features in the ESA PSF. In any case, we cannot use the PSF for analysing the effective area, since only 20 per cent of the total flux is within the Airy disc, so we calculate a ‘revised’ ESA PSF which is background-subtracted in the same way as were the sources and normalized to 1 within the source aperture. Since our observations involved long integrations, in which jitter might significantly blur the PSF, and also because our data reduction did not take into account field distortions, we decided to estimate \( P \) empirically from the HDF observations themselves. \( P \) was estimated by summing the intensities from a number of sources in a square aperture 7 pixels to a side (i.e. 7 arcsec at 6.7 \( \mu m \) and 21 arcsec at 15 \( \mu m \)). The relatively small aperture at 6.7 \( \mu m \) was necessary to avoid including more than one source. At 15 \( \mu m \) we excluded objects near the boundaries and the fainter sources, leaving a sample of six sources, while at 6.7 \( \mu m \) we used all sources in the complete sample. We then normalized such that \( \sum P = 1 \) over the aperture. Some parameters of the PSFs discussed are summarized in Table 1.

Figs 1 and 2 show the effective areas of the surveys to sources of a given flux \( \Omega(S_{\text{lim}} < S) \). Notice that the curves do not pass through the origin in Fig. 2; this is because the sources were detected using a fixed global threshold but the background is estimated locally, hence a source could in principle be detected in a high-background region but then assigned zero or even negative flux.

The faintest flux limit that can provide useful information is defined by the smallest usable area. We choose the smallest useful area to be 200 beams; using Figs 1 and 2 this translates to 38.6 and 255 \( \mu y \) over 1.6 \( \times \) 1.6 and 6.3 \( \times \) 6.3 arcmin\(^2\) respectively. These flux limits include six of the seven 6.7-\( \mu m \) sources and seventeen of the nineteen 15-\( \mu m \) sources. Allowing a smaller area of 40 beams would have suggested flux limits of 30.4 and 161 \( \mu y \), in which case the faintest 15-\( \mu m \) source would be excluded and the faintest 6.7-\( \mu m \) source would be at the flux limit.

At this point we can examine whether our HDF data approach the confusion limit of ISO. The maximum area available at 15 \( \mu m \) is around 18 \( \times \) 18 arcmin\(^2\), and thus the complete sample from Paper II of 19 sources is below the classical confusion limit (more than one source every 40 beams): see Fig. 2. As most of the complete 6.7-\( \mu m \) sample of seven objects have fluxes that are above 40 \( \mu y \), Fig. 1 shows that they are confined to an area \( > 2 \times 2 \) arcmin\(^2\) and thus are above the classical confusion limit. Including the supplementary list from Paper II provides a combined sample of 27 sources, which could well represent a confused sample as the maximum survey area available is \( \sim 6 \times 6 \) arcmin\(^2\).

We use the areas determined with the empirical PSF to construct the observed differential source counts or integral counts:

\[
dN_i = \sum_{j>i} \frac{1}{\Omega(S_{\text{lim}} < S)},
\]

\[
N(> S) = \sum_{j> S} \frac{1}{\Omega(S)}.
\]

The integral counts are shown in Figs 3 to 6 together with models and (in Figs 4 and 6) IRAS counts, which are discussed later. The integral counts are shown rather than differential counts, as these are more useful in practice; however, the data points are not independent and so Poisson 1\( \sigma \) limits are shown as a hatched area. Rigorous statistical comparisons between data and models are best made by

Observations of the HDF with ISO – III

3 STELLAR SOURCE COUNTS

Before moving on to discuss the galaxy counts, a brief word needs to be said about the stellar counts. At 6.7 μm there are no obvious stellar candidates in the complete sample. This is no real surprise, since the HDF was selected to exclude bright stars. Extrapolations from the models of Franceschini et al. (1991) predict 0.38 star arcmin\(^{-2}\) for \(S_{6.7} > 40\) mJy at these latitudes, i.e. 1.9 stars if the HDF area was not biased against stars, reasonably consistent with our finding none. At 15 μm we see one stellar image in the flanking field (ISOHDF3 J123709.8 + 621239). The Franceschini et al. (1991) stellar model would predict 0.1 star arcmin\(^{-2}\), i.e. around one to two stars in this field which is quite consistent with our single detection. This stellar object has been excluded from the galaxy counts.

Figure 1. Area in which the 6.7-μm map is sensitive to sources at a given flux. The dashed line is calculated using the renormalized ESA PSF. On the right is the number of sources that would cause one to exceed the classical confusion limit of 40 beams per source.

Figure 2. Area in which the 15-μm map is sensitive to sources at a given flux. The dashed line is calculated using the renormalized ESA PSF. On the right is the number of sources that would cause one to exceed the classical confusion limit of 40 beams per source.
4 COMPARISON WITH FAR-INFRARED SOURCE COUNT MODELS

4.1 IRAS galaxy counts

We can use the 12-μm IRAS galaxy counts to estimate the bright counts at 15 μm using the Rush, Malkan & Spinoglio (1993) sample. In order to estimate the area of this sample, we had to construct a mask to take account of the IRAS missing strip and regions of high source density that may have been excluded or under-represented. To this end we applied the Queen Mary and Westfield College IRAS Galaxy Catalogue (QIGC) mask (Rowan-Robinson et al. 1991); this cut excluded only 43 galaxies, reducing the sample to 850 objects, and provided an estimate of the area of 6.76 sr. These counts are shown in Figs 4 and 6.

Figure 3. 6.7-μm source counts from the HDF (hatched region). The models at 6.7 μm are based on Pearson & Rowan-Robinson (1996): all components, solid; normal galaxies, dotted; evolving starbursts, dash-triple-dotted; Seyferts 1 and 2, dashed and dot-dashed respectively. The depths probed by other, forthcoming ISO surveys are indicated (ELAIS, Oliver et al. 1997; CAM-D and CAM-S, e.g. Elbaz 1997; Taniguchi, Taniguchi et al. 1997).

Figure 4. 15-μm source counts from the HDF (hatched region). With IRAS 12 μm counts (thick line) at the bright end, from this paper and Rush et al. (1993) (IRAS data shifted to 15 μm using the cirrus spectrum). The models are based on Pearson & Rowan-Robinson (1996): all components, solid; normal galaxies, dotted; evolving starbursts, dash-triple-dotted; Seyferts 1 and 2, dashed and dot-dashed respectively. The depths probed by other, forthcoming ISO surveys are indicated (ELAIS, Oliver et al. 1997; CAM-D and CAM-S, e.g. Elbaz 1997).
4.2 Model galaxy populations

We consider two models of galaxy number counts. Both models have well-defined dust emission spectra, specifically to predict mid- to far-infrared galaxy distributions accurately. In addition, both models include strongly evolving components that are sufficient to explain the steep number counts at 60 μm. The specific populations and spectral energy distributions (SEDs) in the two models are, however, significantly different. Pearson & Rowan-Robinson (1996, hereafter PRR) have described a galaxy population model involving five populations: normal galaxies; starburst galaxies; hyper-luminous galaxies; Seyfert 1 galaxies; and Seyfert 2 galaxies. We have predicted the counts at 6.7, 12...
and 15 μm using these models, ignoring the hyper-luminous population which will have a negligible contribution. Here, starbursts and normal galaxies have 60-μm luminosity functions taken from Saunders et al. (1990); the Seyfert 12-μm luminosity functions come from Rush et al. (1993). Both Seyferts and starbursts evolve as \( L(z) = L(0)(1 + z)^{3.1} \). The SEDs used for these galaxies are based mainly on IRAS data and are described by Pearson & Rowan-Robinson (1996). The model assumes an \( \Omega = 1 \) cosmology. These models were shown to provide a good fit to the IRAS 60 μm counts. As they stand, these models would be unable to account for optical or K-band counts, but would require a low \( \Omega \) or more strongly evolving starburst population. The integral counts predicted by this model are shown in Figs 3 and 4. A second model comes from Franceschini et al. (1994, hereafter AF). The total counts are modelled as the sum of five populations: active galactic nuclei (AGN); starburst galaxies; spiral/irregular galaxies; SO galaxies; and elliptical galaxies. The late-type systems (spirals, irregulars and starbursts) evolve as \( L(z) = L(0)e^{3z} \) (where \( z \) is the look-back time), in an open universe (\( q_0 = 0.15 \)). The early-type systems (ellipticals, SOs) evolve according to Franceschini et al. (1994), i.e. assuming that a bright phase of active star formation at \( z \sim 2-4 \) is obscured by dust quickly produced by the first stellar generations. This same model accounts in some detail for the submillimetre background as estimated by Puget et al. (1996). The AGN number density is set by the local IRAS samples at 12 μm (see Rush et al. 1993). The evolution is calibrated so as to produce the hard X-ray background with a suitable distribution of the dust/gas absorbing column densities. The integral counts predicted by this model are shown in Figs 5 and 6.

The first impression from these figures is of a surprising agreement between the models and the data, considering that, in the case of the 15-μm data, the predictions were made from data 3 decades brighter, while at 6.7 μm there were no previous data with which to normalize the models. In Section 4.4 we will compare the models and observed counts more rigorously, but first we will discuss possible biases in these data.

### 4.3 Simulations of the observed source counts

In any comparison of source counts with models, it is vital to discuss possible sources of bias that might be present. The first issue is the reliability of the detections. Spurious sources arise particularly through non-Gaussian noise features remaining after the data reduction. Using optical associations, Paper IV estimates lower limits to the reliability for the complete samples of 71 and 68 per cent at 6.7 and 15 μm. Thus the reliability could be comparable to the Poisson errors and could be important to this analysis. For the direct comparison with the models we have excluded the non-associated detections, and thus by this estimate of reliability our list is 100 per cent reliable. This method may introduce incompleteness, if we have thrown out genuine sources where the true association has an erroneously low likelihood (as might happen if our positional errors are not well understood). An alternative approach is to include all detections and make a full assessment of the reliability. This requires a good estimate of the noise distribution.

Confusion between faint objects of high source density relative to the beam is an important factor in these surveys. Co-addition of overlapping source profiles means that observed fluxes may be an overestimate of true single-source fluxes. On the other hand, faint sources will tend to be merged together, so decreasing their numbers. We can only estimate this bias with knowledge of the source counts at fainter fluxes. It is thus more appropriate to incorporate confusion into the models than to try to correct the data.

Flux errors will cause objects to be scattered from fainter fluxes above the flux limit and vice versa. Since there are more fainter sources, these are preferentially scattered over the flux limit into our survey. This ‘Eddington’ bias (Eddington 1913) also depends sensitively on counts at faint magnitudes, and so will be included in the models rather than in the data.

The total integral counts predicted at both wavelengths from the first of these models have been used to create 100 synthetic galaxy images using the empirical PSF. These source images were added to the background maps created with random pixel positions (see Paper I). These background maps include uncorrelated noise and sky backgrounds, but have real sources (or structure) suppressed to a negligible level. Some sources of correlated noise may also be suppressed in these background maps, and this is a slight limitation to the simulations.

These resulting images have been passed through the same source detection algorithm as was applied in Paper II, thereby simulating all the possible biases discussed above. The only remaining possible source of incompleteness is from uncertainties in our PSF, which may warrant further investigation.

The average numbers of sources detected from these simulations are listed in Tables 2 and 4 (see later). They do not appear to be significantly different from the model counts on which they are based. Although the simulations are carried out only for the first model, this has similar differential counts to the second at faint fluxes, so we would expect similar behaviour. In neither band do we see any appreciable discrepancies between the models and the simulations over the flux ranges including our data, and we conclude that any biases are small or cancel each other out.

### 4.4 Comparison of models

Using the area of the survey to a given flux limit (Figs 1 and 2), and the number count models of Section 4.2.1, we can estimate the number of sources of any given type that we would expect in this survey. These numbers are summarized in Tables 2–5. Both models are consistent with the total number of associated galaxies. The simulation at 15 μm predicts that there should be 8.37 objects, but our non-associated list includes 16 galaxies. This is a marginally significant excess, and may indicate either that our association requirements are too harsh or that our simulated noise is not realistic; improved understanding of the ISO data in the near future will clarify this. Interestingly, the PRR model predicts that a significant fraction (~ 70 per cent) of the objects should be at fluxes brighter than our brightest source. This discrepancy is also seen in the integral count plots (Fig. 3), where we can also see an apparent difference in slope between the model and the data.
To test whether discrepancies in the count slope are significant, we perform a Kolmogorov–Smirnov (KS) test to assess the probability of the observed fluxes being drawn from the model distribution, estimated using a KS test.

The final column is the probability of the observed fluxes being drawn from the model distribution, estimated using a KS test.

5 P(D) Analysis

Since our maps are close to the ISO confusion limit, it is sensible to examine the low-level fluctuations in the maps on a statistical level. This allows us to investigate source count models below the flux level at which individual sources can be resolved. To this end, we explore the distribution of deviations in flux in a given aperture from the mean level, the P(D) distribution. This analysis avoids the need for any source detection algorithm. The fluctuations in a map about the mean intensity consist of two components. The first is the noise, which will have both positive and negative values, and will have some distribution function which we shall assume is Gaussian. The second component is true fluctuations. These might arise from sources, cosmo-
logical background or Galactic foreground. In all cases this contribution will always be positive and thus skew a symmetric noise distribution. In this case we assume that any major asymmetric component arises from extragalactic sources.

First we select sky regions and construct a histogram of flux deviations in square apertures. These histograms are fitted with both Gaussian distribution functions and the expected distribution functions from the source count models. These model distribution functions are calculated following Franceschini, Toffolatti & Danese (1989), and using the AF model for the source counts discussed above (the differential counts of this model are similar to those from the PRR model below the source detection limit, so the AF model results will be similar for both, and the model provides a better fit to the count distribution at 6.7 \mu m). The differential count distribution is first convolved with a model PSF (in this case a Gaussian PSF is assumed) to give the response function to single sources in the selected aperture. The P(D) can then be calculated assuming that the sources are distributed on the sky as a Poisson process.

Fig. 7 shows the deflection distribution (D in \mu Jy) obtained from a 72 \times 72 matrix of pixels derived from the inner portion of the drizzled mosaic of Paper I. We estimate a sky standard deviation in the inner map outside obvious sources of 16 - 17 \mu Jy aperture⁻¹ (dotted line in Fig. 7). The aperture is 6 \times 6 arcsec² in area, enclosing a disc with a diameter equal to the FWHM of the theoretical PSF. The mean intensity is 0.4 mJy arcsec⁻².

The continuous thick line is the convolution of the Gaussian noise with a model P(D) based on the counts appearing in Fig. 6. The convolved curve provides a very good fit to the data (reduced \chi² ~ 1). A simple Gaussian cannot fit the data, even if the width is increased to \sigma = 18 - 19 \mu Jy aperture⁻¹ with reduced \chi² > 1.5. Thus there is a clear positive signal in the P(D). This means that the background in an extremely deep ISO exposure at 15 \mu m is structured. Such structure is entirely consistent with being due to a smooth extrapolation of the ISO source counts observed above the flux threshold, and confirms the counts.

This P(D) analysis allows us to constrain the models further. The shape of the AF model counts was fixed and the normalization allowed to vary. These constraints are illustrated in Fig. 6.

A similar analysis at 6.7 \mu m demonstrates that a simple Gaussian noise model is sufficient to provide a good fit to the observed P(D). This allows only an upper limit on the normalization of the counts to be determined.

6 DISCUSSION OF POPULATIONS

So far we have not made any use of the fact that our survey was conducted in the Hubble Deep Field and Flanking Fields where there is exceptional photometric and spectroscopic information available. These data allow us to determine the populations detected by ISO. It is still instructive to compare observed and predicted populations, as this may provide clues for improvements to the models.

One of the 6.7-\mu m sources (ISOHDF2 J123646.4 + 621406) selected at 6.7 \mu m has broad emission lines (Paper
IV). This is compatible with the predicted numbers of AGN in both of the models we have considered. Of the remaining four associated objects, only one is compatible with a normal cirrus galaxy and has an elliptical morphology; the others are better fitted with starburst spectra and have spiral morphologies (Paper V).

Excluding AGN, the first of the models (PRR) suggests that at 6.7 μm our sample should have a majority (71 per cent) of normal spiral galaxies with around 28 per cent of starburst galaxies. The expected probability of obtaining the observed one or fewer cirrus galaxies in a sample of four is ~7 per cent. Although the statistics are very poor, this casts further doubt on the validity of the PRR model at this wavelength. The classification of SEDs in Paper V is based mainly on the optical/infrared luminosities. Extra information comes from the expected redshift distribution of these normal galaxies and starbursts, which is shown in Fig. 8. A KS test cannot rule out the possibility that the observed redshifts are drawn from the model distribution even if the redshift of the broad-lined object is included: the probability of the data being drawn from the model distribution is 0.18.

Paper V does not attempt to fit SEDs of the type used for the second model. However, this model predicts that the non-AGN 6.7-μm sources would be 61 per cent ellipticals or S0s and 39 per cent spirals. This is reasonably consistent with the morphologies and SEDs above.

Only three of the 15-μm-selected sources are associated within the HDF itself. Two of these have spiral morphologies and are fitted by starburst spectra, while the third has elliptical morphology and a cirrus spectrum. With such limited statistics this is reasonably compatible with both models. Including the Flanking Field areas, we find in Paper IV that six of the 15-μm-selected sources have associations and redshifts (or photometric redshifts). These are shown in Fig. 9 together with the redshift distribution from the PRR model. Excluding the lowest redshift object (which was excluded from our count analysis as being below the 255-mJy flux limit that was also applied to our model redshift distributions), we find that we cannot rule out these redshifts being drawn from this expected distribution (probability 0.41). This test is hampered by small-number statistics, but also assumes that the objects in the Flanking Fields with redshifts are not biased in any way. Clearly, obtaining spectra for the Flanking Field 15-μm sources is a high priority.

7 IMPLICATIONS FOR FUTURE SURVEYS AND MISSIONS

The fact that we have reached the ISO confusion limit at 15 μm with a sensitivity of around 0.2 mJy has important implications for other surveys and missions, in particular NASA's Small Explorer Mission, the Wide-Field Infrared Explorer (WIRE, http://www.ipac.caltech.edu/wire/). WIRE is due for launch in 1998 September and plans to survey hundreds of square degrees at 12 and 25 μm. The WIRE strategy is divided into three parts: Part I – a moderate-depth survey (60 per cent of the survey time); Part II – a deep, confusion-limited survey (30 per cent of the survey time); and Part III – an ultra-deep, confusion-distribution measurement. The areal coverage and integration times will be designed to achieve these aims, and so the best estimate of the confusion limit is required prior to planning. Currently the WIRE team estimate confusion limits of between 0.067 and 0.15 mJy at 12 μm (http://www.ipac.caltech.edu/wire/sensitiv.html), depending on the evolutionary models. WIRE has a 30-cm mirror with

**Figure 8.** Expected redshift distribution at 6.7 μm within the ISO HDF areas (accounting for the area-dependent flux limit) for the starburst and cirrus components of the PRR model. Overplotted at arbitrary y-position are the redshifts (photometric or spectroscopic) for the five objects with reliable associations in Paper IV. The object at a redshift of 0.96 has broad lines in the optical spectrum. The probability that these data are drawn from the expected distribution estimated using the KS test is 0.54 or 0.18 if the broad-lined object is included.

poorer resolution than ISO, so our results suggest that the confusion limit for WIRE will be brighter than these estimates.

8 CONCLUSIONS

We have investigated the source counts of our ISO observations at 6.7 and 15 μm of the Hubble Deep Field. These are the deepest available in the mid- to far-infrared wavebands, 3 decades fainter than IRAS at 15 μm, and the first ever presentation of extragalactic source counts at 6.7 μm. We reach 50 μJy over $5 \times 5$ arcmin$^2$ at 6.7 μm; at 15 μm we cover $5 \times 5$ arcmin$^2$ to a depth of 200 μJy and around $15 \times 15$ arcmin$^2$ to 400 μJy. In both bands we cover smaller areas to deeper flux limits. These data will be very useful reference points for ongoing ISO surveys: e.g. ELAIS (see e.g. Oliver et al. 1997), the CAM Deep Survey (see e.g. Elbaz 1997), and the survey of Taniguchi et al. (1997). Both the source counts and a $P(D)$ analysis indicate that we have reached the confusion limit of ISO at 15 μm. This will have important implications for the construction of mid-infrared surveys with future space missions such as WIRE. At 6.7 μm we are close to the confusion limit but have not yet reached it. At 15 μm a no-evolution model is ruled out at $> 3\sigma$, providing important confirmation of the strong evolution seen in IRAS surveys at a much greater depth. The counts appear to be steeper than expected from one a priori galaxy evolution model at 6.7 μm, although the significance of this is dependent on our assumptions about the calibration and noise properties of the data and the far-infrared SED of the model, which will improve with time. The $P(D)$ analysis provides constraints on number count models below the level at which we can extract reliable source lists.

Further information on the ISO HDF project can be found on the ISO HDF World Wide Web page (http://artemis.ph.ic.ac.uk/hdf/).

ACKNOWLEDGMENTS

This paper is based on observations with ISO, an ESA project with instruments funded by ESA member states (especially the PI countries: France, Germany, the Netherlands and the United Kingdom) and with the participation of ISAS and NASA. This work was in part supported by PPARC grant No. GR/K98728 and the EC Network programme FMRX-CT96-0068.
