Stand first
The self-controlled case series (SCCS) method is an epidemiological study design for which individuals act as their own control i.e. comparisons are made within-individuals. Hence, only individuals who have experienced an event are included and all time invariant confounding is eliminated. The temporal association between a transient exposure and an event is estimated. SCCS was originally developed for evaluation of vaccine safety, but has since been applied in a range of settings where we may not have exact information on the size of the population at risk or it can be difficult to identify an appropriate comparison group, for example for studies of adverse effects of drug treatments. We provide an overview of the SCCS method, examples of its use, we discuss limitations, assumptions and potential biases that can arise where assumptions are not met along with solutions and examples of good practice.
Introduction

In 1951, Richard Doll and Austin Bradford Hill, wrote to all registered physicians in the United Kingdom to obtain information about their smoking habits. This research was groundbreaking as they were one of the first teams to demonstrate a link between smoking and various diseases (1). Since then, epidemiological study designs, such as cohort and case-control studies, have been widely applied in medical research (w1). There are several situations, however, where standard epidemiological study designs fall short. For example, in the research of adverse effects of vaccines, it can be difficult to identify suitable comparison groups (e.g. if most of the population receives the vaccine). Likewise, for studies on hospital data we may not have information on the exact catchment areas and hence we struggle to find suitable controls for cases of a particular event. In these situations the self-controlled case series (SCCS) method provides an alternative epidemiological study design to investigate the association between a transient exposure and an outcome event. The SCCS method is a case-only method; it has the advantages that no separate controls are required and any fixed confounder is automatically controlled for.(2,3)

In this paper we provide an overview of SCCS methodology and some examples of how the method has been applied in order to give a flavour of the potentials of SCCS. As for any epidemiological study design the SCCS method has some assumptions. We discuss these and identify the key limitations and potential biases.

Self-controlled case series (SCCS) methodology

The SCCS method aims to estimate a relative incidence, which compares the incidence of adverse events within periods of hypothesized excess risk due to exposure with incidence during all other time. Asking ‘when?’ rather than ‘who?’ becomes the key question. Precise timings are needed, so the SCCS method is best suited to acute events and transient exposures for which periods of exposure risk can be clearly defined. Only those who have experienced an event (cases), can contribute any information on when the event occurred, so only data on these individuals need to be collected.

After having identified cases, the first step in setting up the data for SCCS is to define observation periods, these are the study periods for each individual, over which a full history on the timing of events and exposures are available. The next step is to define the periods when exposure may have had an impact within the observation period, for example, a fixed number of days after receipt of a first drug.
prescription or a vaccine; these are known as exposure risk periods. All remaining time within the observation period constitutes baseline exposure periods, to which the exposure risk periods will be compared. SCCS studies may include multiple exposure risk periods as it may be necessary to capture either multiple doses or varying exposure-related risk using several risk periods (which may be of same or different lengths). Observation periods can be further divided according to age groups, seasons and/or any other relevant time-varying factors so they can be accounted for in the analysis. The third step is to ‘map’ events in relation to the different periods identified. Once the data is set up, the final step is to estimate the relative incidence (RI) of events in pre-specified exposure risk periods compared to baseline periods, whilst taking into account the effect of any time-varying confounders such as age groups (w2).

In Figure 1 we illustrate the SCCS setup for an individual with two exposure risk periods and five age groups (panel A) and use this individual to illustrate the output of an SCCS model (panels B, C and D).

Figure 1 here

Comparisons are not made between-individuals as in a cohort or case-control study; estimation is within-individuals. Any factor or characteristic that remains constant over observation periods cancels out of the SCCS model, this includes individual-specific underlying risk and factors such as sex, ethnicity and deprivation. It is in this sense that the SCCS model is self-controlled.

Conceptually, the SCCS method builds on the principles of a cohort study (w1). Individuals are followed through time, the exposure history is fixed and events are random. However, the SCCS method differs in that the total number of events occurring within an individual’s observation period is fixed and follow-up is not censored at an event. Hence all exposures occurring within the observation period - both before and after individuals have experienced the event - are included in the analysis.

A worked example which illustrates how to fit the SCCS model is included in the web materials (w2) and further details of the theory and model fitting are given in Whitaker et al.(3). Below we present two examples of studies that applied the SCCS method. Figure 2 provides a schematic overview of the SCCS study design for each of the studies and the key results.
Example applications of the SCCS method in medical research

Example 1: A possible drug interaction between clopidogrel and Proton Pump Inhibitors (PPI)

Douglas et al. (4) used both a cohort and SCCS approach to study a drug interaction between clopidogrel and proton pump inhibitors (PPI) on the risk of myocardial infarction (MI). The cohort analysis found an increased risk of MI when clopidogrel was combined with a PPI, supporting the notion that an interaction between the two drugs would reduce the effectiveness of clopidogrel (RI 1.30 (1.12-1.50). However, the effect was non-specific as an increased risk of non-vascular death was also seen, suggesting underlying confounding was difficult to account for. The SCCS analysis examined whether the risk of MI was increased in the period when PPI was added to clopidogrel treatment (Figure 2). Thus, the observation period was the duration of clopidogrel treatment, and the exposure risk periods were periods of PPI treatment, which varied in length and number amongst the study participants. SCCS found no increased risk for MI (RI 0.75 (0.55-1.01), suggesting that the underlying confounding had been dealt with through this design.

Example 2: Inflamations and Myocardial Infarction or Stroke

Smeeth et al. (5) aimed to evaluate the association between inflammation and myocardial infarction or stroke. The exposures included inflammatory stimuli: vaccinations and acute infection. SCCS was used because of concerns that people receiving vaccinations may differ from those unvaccinated and likewise people acquiring infections may differ from uninfected people in ways that are difficult to measure and account for. Exposure risk periods were defined up to 91 days following the recording of either an infection or a vaccination, and were further subdivided to allow the relative incidence of events to vary over this period (Figure 2) An increased risk of both MI and stroke was seen over the risk period following either a systemic respiratory tract infection or a urinary tract infection, with the strongest effect in the first 7 days. The risk was still elevated up to 91 days, but appeared to be returning towards baseline. No increased risk was seen following influenza, tetanus or pneumococcal vaccinations. (5) Figure 2 provides the incidence rate ratios for MI following respiratory tract infections.
SCCS assumptions

As for other epidemiological study designs the SCCS model makes certain assumptions that should be met to provide valid and unbiased estimates. Below we outline these assumptions. Table 1 provides a summary of assumption violations that can arise, the solutions and examples of good practice against each.

A. Occurrence of an event should not (appreciably) affect subsequent exposures

A key assumption is that subsequent exposures should not appreciably be affected by previous events. However, this may often be the case. For example, occurrence of an event may delay exposure, the event may be a contra-indication for treatment or the event may result in, or is death. This assumption also means that the event itself should not determine the timing of the end of the observation period. Ignoring this assumption may potentially produce biased estimates, but there are various extensions/moderations to the SCCS method that can mitigate potential biases (Table 1). Note that independent causes of death/end of observation do not cause bias.

Temporary delay or increase in exposure after an event

If the event only temporarily delays exposure this will result in a deficit of events in the period just before exposure that reduces the overall incidence in the baseline period. This results in relative incidence estimates that are biased upwards. One way to correct for this bias is to include a ‘pre-exposure period’ (Table 1.1) just before an exposure. (3) A pre-exposure period can similarly be applied if there is a short-term increase in the probability of exposure after an event (Table 1.2), which would otherwise bias estimates toward the null. A pre-exposure period was included in the clopidogrel and PPI interaction example anticipating that the chance of being started on a PPI could be temporarily altered by having an MI, this is illustrated in figure 2.(4) The pre-exposure period ‘trick’ only works for short-term delay (in relation to the length of observation). If there is long-term delay in exposure after events the methods in the next paragraph may be applied.

No exposure can occur after the event e.g. if the outcome is death

If the outcome is death exposures that might have otherwise occurred after the event will never be known. This is also true if the exposure history is only collected up until the time of the event or if the event is a contra-indication to exposure (Table 1.3). If a fixed length exposure can only occur once, a
simple solution is to define the observation to begin with the start of exposure and finish with the end of study that would have applied had death/censoring not occurred. (3,6) This a priori definition of the observation period means that only exposed cases are included, and if the exposure risk period is of a fixed length then the full exposure history is always known even beyond the time of death/censoring. Alternatively, there is an extension of the SCCS method which produces unbiased estimates given these scenarios. (7)

If the outcome is death, but the exposure is external to the case and fully observable after death e.g. a weather phenomenon, the standard SCCS method can be applied using the full planned observation period, had the case not died.  

*Event increases the probability of death*

If the event carries high mortality, such as myocardial infarction or stroke, then there is a chance that observation periods could be cut short as a direct result of the event. Resulting bias can be in either direction (Table 1.4). If the event mortality is low, bias will be negligible and the situation ignorable. Comparison of results from fitting SCCS models to all cases and excluding those who died can be made; major differences would suggest bias. Bias may be corrected by fitting an extension that involves modelling post-event survival times. (8)

**B. Event rates are constant within intervals**

Event rates are assumed to be constant within each defined period. While such an assumption is often unrealistic, it is convenient, makes relative incidence estimates easy to interpret and is commonly used in other study designs. Control of strong age or season effects is important and SCCS models with greater flexibility have been developed. (9,10)

**C. Events must be independently recurrent or rare**

The SCCS method was developed for *independent* recurrent events, but it has been demonstrated that the method is valid for non-recurrent events when the risk of occurrence over the study period in the entire cohort is 10% or less. (8) A test for independence has been developed. (11) If events are dependent a simple solution is to study just first events (Table 1.5). An extension for which events may depend on the prior event history exists. (12)
Final remarks

With this paper we have sought to demonstrate how the self-controlled case series method provides an alternative to standard epidemiological designs when investigating associations between a transient exposure and an outcome event. A major strength of the SCCS is that it is self-controlled and accounts for any factor or characteristics that remains constant over observation period. Thus, where uncertainty over the control of fixed confounders exists in a cohort or case-control study, SCCS may provide a superior design, given careful thought is made to applying the methodology correctly.

Summary

- The self-controlled case series method provides an alternative to established epidemiological designs.
- SCCS is best suited to acute recurrent or non-recurrent events and transient exposures for which precise timings are available.
- Estimation is within-individuals and no separate controls are required, hence the method is self-controlled and time invariant factors are cancelled out.
- Follow up is not censored at the event, so when events can impact on subsequent exposure, care must be taken to ensure analyses are carried out that eliminate or minimize bias.

Linked information

The Open University host a website for the Self-controlled Case series methodology with example datasets and code for analysis in Stata, SAS, R, Genstat and GLIM.

Statements

This paper was written jointly by Irene Petersen (IP), Ian Douglas (ID) and Heather Whitaker (HW). HW is one of the leading experts in SCCS and has been involved in the development of the SCCS methodology from 2004 and onwards. ID and IP have applied the SCCS in a range of settings and keep encouraging colleagues and students to consider the application of SCCS in (pharmaco)-epidemiological
studies. HW was supported by an MRC methodology grant (MR/L009005/1). None of the authors have any competing interests. Guarantor HW.

<tbody>
<tr>
<td>1) Event temporarily decreases the probability of exposure</td>
<td>Include a pre-exposure period</td>
<td>Stowe et al studied the risk of infections after mumps, measles and rubella (MMR) vaccination. Vaccination is delayed when a child has an infection; a 14-day pre-exposure period was included to allow for this. (13)</td>
</tr>
<tr>
<td>2) Event temporarily increases the probability of exposure</td>
<td>Include a pre-exposure period</td>
<td>Gibson et al studied the association between prescription medications and motor vehicle crashes. A 4-week pre-exposure period was included since some medications may be used to treat anxiety or pain caused by the crash. (14)</td>
</tr>
<tr>
<td>3) No exposure can occur (or is observed) after the event</td>
<td>For single exposures that cannot be repeated, begin the observation period at exposure, so only exposed cases are included. End observation at the planned end. For single or multiple exposures, use the method outlined in Farrington et al. (7)</td>
<td>Hubbard et al studied the association between first bupropion prescription and sudden death. The observation period began with date of first prescription and ended (beyond death) with the date of last data collection for the cohort. At the time, bupropion could only be prescribed as a single course of treatment.(6) Dodd et al studied the association between influenza vaccination and Guillain Barré Syndrome (GBS). Some practitioners will not vaccinate previous GBS patients.(15) Various analyses were performed: standard SCCS, vaccinated cases only, and the method outlined in Farrington et al. (7)</td>
</tr>
<tr>
<td>4) Event increases the probability of death</td>
<td>Undertake suitable tests or sensitivity analyses excluding cases who died as a result of the event. If necessary, use the methods outlined in Farrington et al. (8) to adjust for bias.</td>
<td>Langan et al studied the risk of stroke following herpes zoster infection. A sensitivity analysis was performed excluding cases who died within 90 days of stroke, findings were not modified.(16) Brauer et al. studied the association between antipsychotic drugs and myocardial infarction using both the methods outlined in Farrington et al. (8) and a standard SCCS analysis. There was little difference in results.(17)</td>
</tr>
<tr>
<td>5) Recurrences of an event are not independent</td>
<td>Study the first event only</td>
<td>Recurrence of stroke is not independent of the first occurrence, so only a first stroke event can be studied. In a study on the risk of stroke, Langan et al. began the observation period 12 months into follow up time to ensure first stroke events had been correctly identified.(16)</td>

Figure 1 Graphic illustration of the SCCS model output using a fictive individual with two exposure risk periods and five age groups.

Panel A: An individual observation period segmented by two exposure risk periods (red boxes, labelled exposure risk status 1) and five age groups (blue boxes, labelled 0 to 4). The baseline categories for age and exposure are labelled age group 0 and exposure risk status 0 respectively.

Panel B: Exposure-related relative incidences. Note for the baseline category the relative incidence is 1 and the exposure relative incidence is arbitrarily set to 1.8.

Panel C: Age-related relative incidence on age groups 1-4 compared with age group 0. The age relative incidences for age groups 1-4 have been set to 2, 1.5, 1.2 and 0.5 respectively.

Panel D: Overall profile of relative incidence on each of the nine intervals, this is the age-related relative incidence multiplied by the exposure-related relative incidence.
