AKARI DEEP FIELD SOUTH: SPECTROSCOPIC OBSERVATIONS OF INFRARED SOURCES

Chris Sedgwick, Stephen Serjeant, Chris Pearson, Shuji Matsuura, Mai Shirahata, Hideo Matsuhara, Lucia Marchetti, Glenn J. White, Mattia Vaccari, Ivano Baronchelli, Giulia Rodighiero, Bunyo Hadsukade, David L. Clements, and Simon Amber

1. INTRODUCTION

The AKARI Deep Field South (ADF-S) is located close to the South Ecliptic Pole and has the advantage of very low cirrus and zodiacal dust, which makes it an ideal field for extragalactic observations. The original field was observed by the AKARI Space Telescope (Murakami et al. 2007) in the far-infrared (Matsuhara et al. 2006; Matsuura et al. 2011) and covered a rectangular area of \( \sim 12 \text{ deg}^2 \) centred on RA 04 44 00, Dec -53 20 00 (J2000).

We will describe the results of an AAOmega spectroscopy campaign using targets chosen primarily from the AKARI catalogues in the central 3.14 deg\(^2\) of this field from which we have identified redshifts for 404 sources. Multi-wavelength observations made in this field will be available shortly enabling spectral energy distributions (SEDs) to be fitted to these sources.

2. METHODS: AAOmega SPECTROSCOPY

2.1. Choice of targets

Our targets were chosen primarily from sources in three AKARI catalogues: the 90 \( \mu \text{m} \) catalogue of AKARI’s Far-Infrared Surveyor (FIS; Kawada et al. 2007) and the 15 \( \mu \text{m} \) and 24 \( \mu \text{m} \) catalogues of AKARI’s InfraRed Camera (IRC; Onaka et al. 2007). We also chose targets from submillimetre catalogues ASTE/AzTEC (Hatsukade et al. 2011) at 1100 \( \mu \text{m} \) and the Balloon-borne Large Aperture Submillimeter Telescope (BLAST; Valiante et al. 2010) at 250, 350 and 500 \( \mu \text{m} \).

Sources were targeted only where we could find opti-

2.2. Observations and data reduction

We used AAOmega, the fibre-fed optical spectrograph (Sharp et al. 2006) at the Anglo Australian Observatory to obtain optical spectra of our targets. Observations were made in 2007/08 as shown in Table 1. Gratings were 385R and 580V with central wavelengths 7250Å and 4800Å, and wavelength resolution \( \lambda/\Delta \lambda = 1300 \). We successfully obtained 1,492 spectra.

The spectra were reduced using the standard AAOmega pipeline 2dflr data reduction software (Crook et al. 2004). The combined spectra have a range of about 3800 - 8800Å. We used IRAF routine onedspec/splot to identify redshifts. We also wrote a graphic user interface (GUI) in IDL in order to visually inspect the spectra by moving emission line templates across the spectra, and also to identify local lines and artefacts present in the data. As described in Sedgwick et al. (2011), we found several local artefacts in many of the spectra, often relating to neon emission from street lighting in a nearby town and identified these in our GUI to avoid false identifications.

3. RESULTS

3.1. Redshift identifications

The redshifts identified by atomic emission lines fall into three bands (see Table 1). The largest number of sources were found at \( z \leq 0.345 \) and could be identified by their \( \text{H} \alpha \lambda 6563 \) line, which fell into our spectral range at this redshift. The nearby [NII] \( \lambda \lambda 6548, 6583 \) lines were usually also observed, as was the [SII] doublet \( \lambda \lambda 6716, 6731 \) unless it was redshifted out of range.

Secondly, sources at \( 0.345 < z \leq 1.0 \), for which the strongest observable lines are the three \( \text{H} \beta/\text{[OIII]}/\text{[OIII]} \lambda \lambda 4861, 4958, 5007 \) emission lines (up to about \( z = 0.74 \)). Redshifts were taken only where there was
Figure 2. Examples of three spectra at different redshifts and the two detections from Lyα lines. The potential emission lines at this redshift are full-length dotted lines; the local artefacts are short solid lines from top of spectra (shown in colour online). Flux is subject to final calibration. From top: (a) FIS408, redshift $z = 0.179$, from Oct-07 fibre 22. (b) IRC3, $z = 0.642$, Oct-07 fibre 133. (c) IRC6, redshift $z = 1.595$, Jan-08 fibre 122 (all unsmoothed). (d) IRC22 at redshift $z = 2.357$ Oct-07 fibre 59 (boxcar smoothed, 3 pixels); relative fluxes of the three peaks should be 100:63:29 (Francis et al. 1991). (e) L15UM257 at $z = 2.858$, Jan-08 fibre 265 (unsmoothed).

Evidence for these three emission lines. In addition, the asymmetrical [OII] emission line resulting from the close doublet $\lambda 3726, 3729$ was often found at the same redshift to support the identifications.

Thirdly, after a gap in the redshift range without strong emission lines, there is a possibility of identifying several broad emission lines at redshifts $z > 1$. At about $1.0 < z < 1.7$ two strong lines are available: CIII$\lambda 1909$ and MgII $\lambda 2798$. Above $z \sim 2.3$, Ly$\alpha \lambda 1216$ comes into range, and up to $z \sim 3$ this can be supported by CIV $\lambda 1549$ and CIII$\lambda 1909$.

A total of 404 redshifts were measured for the 1,492 sources targeted (see Table 1). Examples of spectra obtained showing the redshift identifications in these three regions, and the spectra with the two highest redshifts, are given in Figure 2.

### 3.2. Flux calibration of spectra

The AAOmega spectra were not calibrated (this part of the reduction pipeline was not in place, and no flux calibration data were observed on the five nights). To enable calibration, we are using broadband photometric data from the LaSilla/WFI R-band catalogue for the field (Baronchelli et al., in prep). Choosing sources at $z < 0.1$ so that the H-alpha emission line falls within the high-throughput region of the WFI filter, and applying the AAOmega grating throughputs and WFI R-band filter, we integrate the AAOmega counts over the WFI broadband region and compare the result to the WFI flux. When results are finalised, we anticipate providing line luminosities for all observed lines.
4. DISCUSSION

4.1. Luminosity function

An earlier paper (Sedgwick et al. 2011) used 130 of these spectroscopic-redshift sources to prepare a luminosity function of star-forming galaxies selected at 90 µm at 0 < z < 0.25. The result agreed well with a prediction by Serjeant & Harrison (2005), and also with predictions from a model by Gruppioni et al. (2011).

4.2. Proportions AGNs and LIRGs

For the 320 sources at z ≤ 0.345, the FWHM of the Hα lines showed only two sources over 1000 km s⁻¹, and the majority under 500 km s⁻¹, suggesting few of these sources are dominated by AGN emission. Another method for discriminating between AGNs and star-forming galaxies (SFGs) is the BPT diagram (Baldwin et al. 1981), shown in Figure 3 (top). This shows a minority (∼13%) of sources dominated by AGN, with a significant fraction in the intermediate region showing evidence of both SFGs and AGNs. This is broadly consistent with previous results e.g. Manners et al. (2004), who found 19% for 15 µm-selected sources and Caputi et al. (2007), who found 17% for 24 µm-selected sources.

4.3. Star formation rates and Balmer decrement

Star formation rates over ∼ 10³ M⊙yr⁻¹ were found for higher-redshift sources; local galaxies were typically ≤ 20 M⊙yr⁻¹ (see Fig. 3, middle). The Balmer decrement Hα/Hβ is shown in Fig. 3 (bottom) for sources at z < 0.345. This shows very slight increase with redshift, and a median decrement of 5.9 with a large scatter.

4.4. Multi-wavelength data for spec-z sources

Multi-wavelength data already available for the ADF-S include AKARI-FIS (Shirahata et al. in prep.), AKARI-IRC (Davidge et al. in prep.), Spitzer-MIPS (Clements et al. 2011; Scott et al. 2010), BLAST (Valiante et al. 2010), Herschel-SPIRE (HerMES DR2; Oliver et al. 2012), submillimetre ASTE/AzTEC (Hatsukade et al. 2011) and radio ATCA (White et al. 2012) as well as studies matching AKARI to public data (Malek et al. 2010, 2014). Data will soon be available for Spitzer-IRAC (Baronchelli et al. in prep.), Herschel-PACS (Hatsukade et al. in prep.; HerMES), and optical and NIR data from CTIO, WFI, VST and VISTA in the UBVIRgizYJHKs bands. The optical and NIR will enable SED template fitting to our spectroscopic sources, so that further properties including age, mass, metallicity and extinction may be estimated for our sources.

Figure 3. Top: BPT diagram for the 192 sources for which the two ratios have been determined by the AAOmega spectroscopy. The area between the solid line (Kauffmann et al. (2003)) and the dashed line (Kewley et al. (2006)) indicates composite AGN-SFG sources. Middle: Plot of FIR luminosity and SFR based on L_FIR for sources detected at 24 µm by Spitzer-MIPS in ADF-S. L_FIR was estimated using the M82 SED, and SFR (right-hand axis) was estimated from this using the Kennicutt (1998) formula. Bottom: The Balmer decrement for sources at z < 0.345. Note indicative error bar on right of figure.
ACKNOWLEDGMENTS

This research is based on observations with AKARI, a JAXA project with the participation of ESA. This work was funded in part by STFC (grant PP/D002400/1), the Royal Society (2006/R1-IJ), the Sasakawa Foundation (3108) and KAKENHI (19540250 and 21111004).
