1. Introduction

Autophagy is an evolutionarily conserved degradation/recycling process reliant on lysosomal hydrolases and acid lipases, operating alongside proteasomal degradation, mediating the turn-over of damaged, excess or unwanted cellular constituents, including long-lived proteins, protein aggregates, lipids and complete organelles, like mitochondria and peroxisomes [1]. In addition, autophagy plays a role in maintaining cellular metabolism, defence towards invading microorganisms, and is involved in cell fate and tumour suppression and survival [2]. Autophagy can mediate the non-selective degradation of cytoplasmic components as well as the selective degradation of certain subsets of cellular components, including lipids (‘lipophagy’; [3]), endoplasmic reticulum (‘reticulophagy’ or ‘ER-phagy’; [4]), mitochondria (‘mitophagy’; [5]), and peroxisomes (‘pexophagy’; [6]) [7]. Excessive autophagy can lead to cellular demise via a Na⁺/K⁺-ATPase-regulated form of cell death via a process termed ‘autosis’ [8–10]. Yet, in most situations, autophagy functions as a pro-survival process allowing the cells to cope with damage, stress or infection, and to maintain energy levels and anabolic processes in periods of starvation [11]. Unfortunately, the pro-survival and degradative functions of autophagy can be usurped or dysregulated in pathological states, such as cancer and neurodegenerative diseases, thereby exacerbating unwanted outcomes [12,13].

Autophagy is initiated by signalling pathways that trigger the formation of a membrane invagination, described as an omegasome, pre-dominantly on the surface of the endoplasmic reticulum (ER), although other membranes may also be involved [14]. The nascent autophagic vesicle progressively enlarges into an independent, or ER-associated, phagophore that traps cellular material and eventually closes upon itself to give a discrete autophagic vesicle (at this stage called an autophagosome). Via cytoskeleton-dependent motion, autophagosomes engage and fuse with lysosomes in a Ca²⁺-sensitive manner [15] (after which they are called autolysosomes), thereby delivering the unwanted...
cellular contents to the lysosomal hydrolases and lipases that will degrade them. Autophagy can be triggered in a host of different ways; most notably by withdrawal of nutrients, amino acids or growth factors, or by pharmacological compounds such as rapamycin, which inhibit mechanistic target of rapamycin (mTOR; a suppressor of autophagy), or AICAR (5-Aminooimidazole-4-carboxamide ribonucleotide), which activates AMPK (an inducer of autophagy). Cells display a constitutive, basal level of autophagy that is necessary for homeostasis. Basal autophagy has characteristics in common with autophagy that has been triggered [16].

A key factor for the initial formation of autophagosomes is Beclin 1 (the mammalian ortholog of Atg6), which is proposed to interseck with various Ca2+ signalling pathways, as described below. To stimulate autophagy, Beclin 1 interacts with a multi-protein complex that includes Vps34 (‘vacular protein sorting’), a class III phosphatidylinositol 3’-kinase. Vps34 catalyses the production of phosphatidylinositol-3-phosphate (PI3P) and thereby demarcates omegasome/phagophore nucleation sites [17,18]. PI3P production is a common requirement for all triggers of autophagy, and Vps34 deficiency inhibits autophagy [19].

mTOR is a component of two multi-protein signalling complexes denoted mTORC1 and mTORC2. Whilst there is some overlap in the cellular roles of these complexes, the former complex predominantly regulates functions including protein synthesis, cellular proliferation and autophagy, whilst the latter complex regulates cytoskeletal structure, cellular metabolism, cell survival and response to cells to insulin [20–22]. In growth-promoting conditions, mTORC1 phosphorylates, and thereby inhibits, the activity of a downstream kinase, unc-51-like kinase (ULK1; mammalian ortholog of Atg1), which is necessary for autophagosome formation [23]. The activity of mTORC1 declines in response to depletion of amino acids, growth factors, reduced cellular energy levels or chemical inhibitors like rapamycin and Torin 1 [24]. In addition, mTORC1 can be regulated through its reversible association with lysosomes in a nutrient-sensitive manner [25]. AMPK, which is activated by an increased cytosolic AMP concentration in energy-compromised cells and by Ca2+-dependent kinases, also phosphorylates ULK1, but in this case leading to activation and autophagy [23,26] (Fig. 1). In addition to this, ULK1 protein levels are dynamically regulated during prolonged starvation [27,28]. Activated ULK1 becomes ubiquitinated by the E3 ligase NEDD4L, resulting in proteasomal ULK1 degradation and thereby limiting autophagic flux after an initial autophagy response. ULK1 is re-synthesized in an mTOR-dependent manner, but also kept inactive due to mTOR phosphorylation.

Ca2+ is a ubiquitous messenger that controls a host of cellular functions [29,30]. In particular, Ca2+ signals have been implicated in cell fate decisions, including proliferation, differentiation, migration, and cell death [31,32]. The cellular Ca2+ signalling toolkit contains a substantial array of components for causing Ca2+ signals and transducing their functional effects. Through the expression of selective components of the toolkit, different cell types display Ca2+ signals that fit with their physiological functions. There can be considerable variation in the kinetics, frequency, amplitude and spatial extent of Ca2+ signals in different cell types, as well as their outcomes. The variation in cellular Ca2+ signals, and how they are transduced, is an essential aspect of the ability of Ca2+ to be a universal messenger [33–35].

The reliance of lysosomal protein degradation on cellular Ca2+ stores was suggested more than three decades ago [36]. Yet, exactly how Ca2+ regulates autophagy is still a subject of intensive investigation. A search for publications with the words ‘autophagy’ and ‘Ca2+’ returns ~1000 results at the time of writing this article. However, whilst these publications may invoke pro- or anti-autophagic functions for Ca2+, many studies are difficult to interpret because of the imposition of non-physiological Ca2+ signals or use of pharmacological reagents with pleiotropic actions, as has been discussed previously [37]. For example, prolonged application of thapsigargin to block sarco-endoplasmic reticulum Ca2+ ATPases (SERCAs) has been employed to evoke a sustained cytosolic Ca2+ elevation, but will also trigger ER stress through chronic depletion of intracellular Ca2+ stores and the accumulation of unfolded proteins [31,38]. Similarly, prolonged use of ionomycin, a Ca2+ ionophore, has been used to induce long-lasting cytosolic Ca2+ signals, but will also deplete intracellular Ca2+ stores, eventually depolarise mitochondria and cause fragmentation of organelles [39]. These comments are not meant to imply that there is no value in using reagents such as SERCA inhibitors and ionophores, but it has to be born in mind that physiological cellular Ca2+ signals are typically brief, pulsatent events that do not trigger adverse outcomes. Deviation from a physiological paradigm may activate autophagy, but potentially as a result of cellular stress and adaptive responses [38] and not necessarily because of Ca2+ signals that would occur naturally. It is perhaps not that surprising that some data derived from the use of pharmacological reagents (e.g., thapsigargin) have yielded conflicting hypotheses about signalling mechanisms involved in Ca2+-activated autophagy. This review is an attempt to assimilate a rather wide and disparate topic into coherent segments. In most of the sections below, we review evidence for or against the role of a particular Ca2+ source/signal in the regulation of autophagy, and attempt to coalesce the evidence into some sort of conclusion. Some themes, for example Ca2+ release mediated by inositol 1,4,5-trisphosphate receptors (IP3Rs), arise in multiple sections as they are relevant to autophagy in different ways. We direct the interested reader to other reviews that have discussed both the pro- and anti-autophagic roles of cellular Ca2+ signalling [40–43].

2. Measuring Ca2+ signalling and autophagic flux

A technique that is commonly employed to study the induction of autophagy is the accumulation of the mammalian protein ‘light chain of the microtubule-associated protein Y’ (ortholog of Atg8; more typically referred to as LC3) [44]. When autophagy is activated, LC3 is conjugated to phosphatidyethanolamine and thereby recruited to autophagosomal membranes. Using Western blotting, the lipidated (autophagic) form of LC3 can be detected as a band with an apparently lower molecular weight (LC3-II, 16 kDa) compared to the non-lipidated form (LC3-I, 18 kDa). When expressed in cells under basal, nutrient-rich conditions, a fluorescently-tagged version of LC3 (e.g., GFP-LC3) has a largely diffuse appearance. Autophagy induction leads to the formation of multiple brightly fluorescent GFP-LC3 punctate of a few micrometres in diameter. These punctae reflect LC3-II molecules associating with the nascent phagophore and autophagosomal vesicles, as mentioned above [45]. When the vesicles mature, the LC3-II molecules on the outside of the autophagosomes are delipidated, released and recycled to support further phagophore formation [46]. When the autophagosomes fuse with lysosomes, the acidic conditions within the lumen of the autolysosome quench the fluorescence from GFP and the punctae are no longer evident. A refinement of this approach has been to use LC3 tagged with both GFP and a red fluorescent protein (e.g. mCherry or mRFP) [47] (Fig. 2A–C). The red fluorescence is not quenched by the acidic conditions in the lumen of the autolysosome, but eventually dissipates due to protein degradation. This tandem fluorescent reporter allows visualisation of phagophore membranes and autophagosomal punctae as punctae with overlapping green and red fluorescence, and mature autolysosomes as punctae with red fluorescence only [44]. The tandem reporter can also help in establishing that autophagic flux is truly occurring, and that the accumulation of autophagic vesicles is not due to a blockade in their processing.

We have found both the GFP-LC3 and mCherry-GFP-LC3 probes to be compatible with ratiometric imaging of cytosolic Ca2+ signals using Fura-2 (unpublished data). For confocal Ca2+ imaging, which requires visible wavelength fluorophores, a Ca2+ indicator such as Cal590/630 would be suitable to multiplex with LC3 tagged with either GFP or a red fluorescent protein. It is therefore possible to follow cytosolic Ca2+ changes and autophagic flux in the same cells, in real time, during long-
are more rapidly recycled[50], might give an alternative quantitative
nositide interacting 1 (WIPI-1; mammalian ortholog of Atg18), which
fl
with phagophore/autophagosomal membranes for some time, and

events such as development of the nascent phagophore membranes
view of the induction of autophagy through visualising more proximal
controls of autophagy do not actually show Ca2+
lighting and cell stress in unknown ways, followed by a single time point
determination of autophagy many hours later. Moreover, since stimuli
such as hormones, thapsigargin and ionomycin trigger Ca2+ signals
within tens of seconds, and the formation and processing of autophagic
vesicles occurs over minutes[44], it is unclear why such reagents would
be arbitrarily applied for many hours as they are then most likely to
have multiple cellular effects. An ideal approach could be to find the
least exposure time required for a significant effect on autophagy, and
where possible to use real-time visualization of both cellular Ca2+ and
autophagic flux. Such considerations may simplify some of the appar-
ently contradictory literature.

It is well established that care needs to be taken in the assessment of
autophagic flux using assays such as fluorescently-tagged LC3 probes
and Western blotting for LC3-II[44]. For example, LC3 can associate
with endosomal vesicles that are not allied with canonical autophagy
[48] and also with protein aggregates[49]. Moreover, LC3-II associates
with phagophore/autophagosomal membranes for some time, and
many overlapping punctae can accumulate in cells. Whereas, other
fluorescently-tagged proteins, such as WD repeat domain, phosphoi-
nositide interacting 1 (WIPI-1; mammalian ortholog of Atg18), which
are more rapidly recycled[50], might give an alternative quantitative
view of the induction of autophagy through visualising more proximal
events such as development of the nascent phagophore membranes
[51]. Treatment of cells with thapsigargin was found to cause an
increase in WIPI-1-labelled phagophore/autophagosomal membranes
[52,53], which is consistent with a Ca2+-activated induction of au-
thophagy. Moreover, it is important to note recent work indicating that
bulk autophagy of cytoplasmic contents can be independent of LC3, and
that autophagic-lysosomal flux does not always phenocopy autophagic-
lysosomal LC3 processing[54,55]. Rather, it was shown that cyto-
plasmic cargo sequestration by autophagy is dependent on GABARAPs,
a subfamily of Atg8 proteins[54]. Hence, analysis of autophagic flux by
macroautophagic cargo sequestration using the transfer of the cytosolic
protein lactate dehydrogenase to autophagic vesicles should be con-
sidered as an alternative[56].

It has been shown that agents used to elicit, or inhibit, Ca2+ signals
can have unintended consequences for autophagy. For example, many
studies have used thapsigargin to trigger autophagy in a Ca2+-depen-
dent manner. However, prolonged treatment of cells with thapsigargin
may halt autophagic flux by blocking autophagosome/lysosome fusion,
thereby increasing the persistence of LC3-II-labelled autophagosomes
[53,57,58], but see[59]. Under such a condition, the accumulation of
LC3-II-labelled autophagosomes may reflect on-going basal autophagy,
and not the triggering of autophagy by Ca2+. The potential blockade of
autophagic flux by thapsigargin (or other SERCA inhibitors) may be an
unhelpful experimental outcome, depending on the nature of the study
being undertaken. However, the action of thapsigargin on autophagoge-
some/lysosome fusion may correlate with the pathological blockade of
autophagic flux in hepatocytes during obesity. The accumulation of
saturated fatty acids in hepatocytes during obesity has a similar in-
hibitory action on SERCA, and consequently leads to accumulation of
protein aggregates and lipid droplets, which can be abrogated by Ca2+
channel blockers[60].

Control experiments that help to establish genuine autophagic flux
from aberrant accumulation of LC3-II can be performed using estab-
lished blockers of autophagy induction and flux, such as 3-methylade-
nine (3-MA) and bafilomycin[44,61]. 3-MA (or wortmannin) inhibits
Vps34 and therefore prevents the production of PI3P necessary for

Fig. 1. Illustration of some of the ways in which Ca2+ has been proposed to regulate the triggering
and progression of autophagy. The illustration de-
picts some aspects of the canonical autophagy
pathway and the subsequent processing of autopha-
gosomes, and indicates sites at which regulation by
cytoplasmic Ca2+ may occur. Some of the proposed
Ca2+-regulated steps have been suggested on the
basis of inhibition by BAPTA-AM, whilst the source
and characteristics of many of the Ca2+ signals are
unknown.
autophagy. However, long term treatment with 3-MA can trigger autophagy due to its additional inhibition of class I PI3-kinases, which produce PIP3 (phosphatidylinositol 3,4,5-trisphosphate) and activate Akt/mTOR signaling [62]. Also, there may be situations, such as the activation of autophagy by leucine rich repeat kinase 2 (LRRK2), where 3-MA is not effective [26,63]. Bafilomycin inhibits V-type ATPases, and thereby causes the de-acidification of lysosomes so that the luminal hydrolases cannot work, and it also prevents autophagosome/lysosome fusion with more prolonged incubation [64,65]. An increase in LC3-II accumulation (or other autophagy markers) in the presence of bafilomycin is usually taken as evidence of autophagic flux (Fig. 2). However, it has been shown that bafilomycin inhibits SERCA activity [66,67], and may therefore act just like thapsigargin in triggering a cytosolic Ca^{2+} signal with concomitant emptying of intracellular Ca^{2+} stores, and thereby blocking autophagosome/lysosome fusion. The diameter and shape of autophagic vesicles is a characteristic that can be relatively

![Fig. 2. Quantitation of autophagy using a mCherry-GFP-LC3 reporter, and induction of autophagy by expression of an IP3 5′-phosphatase enzyme in HeLa cells. Cells were stably transfected with a plasmid encoding mCherry-GFP-LC3. Panel A illustrates how this reporter can be used to assess autophagic flux. GFP is quenched in the acidic lysosomal compartment, whereas mCherry remains fluorescent. Therefore, autophagosomes were evident as punctae with both green and red emission (from GFP and mCherry, respectively) and autolysosomes were evident as punctae that just had red emission (from mCherry only). Panel B shows representative images of cells in amino acid/growth factor-replete medium supplemented with rapamycin (1 μM) for 4 h. Panel C is a quantitative representation of the effects of rapamycin and rapamycin + bafilomycin (BafA1) on numbers of green and red punctae calculated from experiments such as that shown in Panel B. Rapamycin and BafA1 increased the total number of punctae (whether green or red). BafA1 also reduced the proportion of red only punctae, consistent with a reduced autophagic flux. The data are mean ± S.E.M of 3-4 experiments (40-80 cells per condition). The data were analysed with one-way ANOVA. ** indicates p < 0.01 and **** indicates p < 0.0001. Panel D depicts control untransfected HeLa cells (left-hand images) and HeLa cells transfected with mCherry-tagged IP3 5′-phosphatase (12-h transfection; right-hand images), showing an increased number of GFP-LC3 punctae. The HeLa cells were maintained in serum-containing medium throughout. The scale bars in all Panels B and D indicate 10 μm.](image-url)

<td>Ca(^{2+}) → CaMKKβ → AMPK → mTOR → autophagy</td>
<td>Crushing of optic nerves was used to study mechanisms of axonal degeneration. Nerve crushing lead to the accumulation of autophagosomes for up to 6 h, which could be inhibited by 3-MA. Autophagy was dependent on Ca(^{2+}) influx, since Ca(^{2+}) channel inhibitors reduced both the crush-induced cytosolic Ca(^{2+}) elevation and autophagosome numbers. In this context, autophagy exacerbated neuronal demise, since application of 3-MA delayed some aspects of axonal degeneration. Immortalised hepatocytes were treated with thapsigargin to deplete intracellular Ca(^{2+}) stores and induce ER stress. Autophagosomes accumulated as a consequence of ER stress and the accumulation of misfolded proteins. In this context, autophagy was pro-survival, since application of 3-MA reduced cell survival following thapsigargin treatment. Proposed mechanism: Ca(^{2+}) → PKC → autophagy Infection of HeLa cells with the apicomplexan parasite Toxoplasma gondii triggered autophagy that was inhibited by BAPTA-AM. The induction of autophagy was delayed compared to infection, suggesting that it was triggered by metabolic demand caused by the parasite. Consistent with this notion, inhibiting autophagy slowed Toxoplasma growth. Calcium phosphate particles, as used in cell transfection, evoked a reversible, concentration-dependent increase in autophagic vesicle accumulation in HEK293 and MEF cells that was inhibited by BAPTA-AM. In this context, an inhibitor of CaMKKβ (STO-609) was ineffective at blocking autophagy. Basal autophagy in primary hepatocytes was blocked by chelating extracellular or intracellular Ca(^{2+}), consistent with the need for a permissive cytosolic Ca(^{2+}) concentration. However, SERCA blockers and Ca(^{2+}) ionophores gave a concentration-dependent inhibition of autophagy. These data led the authors to conclude that autophagy was dependent on Ca(^{2+}) sequestered within intracellular stores. Starvation-induced autophagy in HeLa cells was blocked by BAPTA-AM, and also by inhibiting IP3Rs. Starvation enhanced ER Ca(^{2+}) store loading and caused sensitisation of IP3-R-mediated Ca(^{2+}) release. Oxidized low-density lipoproteins triggered store-operated Ca(^{2+}) entry in endothelial progenitor cells, which subsequently led to induction of autophagy via the proposed mechanism: Ca(^{2+}) → CaMKKβ → AMPK → autophagy. Stimulation of various cell types with thapsigargin for 3–6 h triggered autophagy, which was further enhanced by bafilomycin (and therefore suggested not to be due to blockade of autophagic flux). The thapsigargin-induced autophagy was inhibited by BAPTA-AM. The authors suggested that inhibition of autophagy was independent of mTOR, and only partly dependent on AMPK. Withdrawal of amino acids, which triggers autophagy, was found to induce a cytosolic Ca(^{2+}) elevation in several cell types. Proposed mechanism: Ca(^{2+}) → CaMKKβ → AMPK → ULK1 → autophagy. Stimulation of neuronal cells with resveratrol increased cytosolic Ca(^{2+}) levels and promoted autophagic clearance of amyloid beta. Proposed mechanism: Ca(^{2+}) → CaMKKβ → AMPK → autophagy. Starvation induced a cytosolic Ca(^{2+}) signal from lysosomal TRPML1 channels on lysosomes from HeLa cells (but, see [101]). The Ca(^{2+}) signal activated the phosphatase calcineurin, which dephosphorylated the transcription factor TFE3 thereby allowing it to translocate to the nucleus and initiate gene expression. In addition, the lysosomal Ca(^{2+}) signal increased the number of PIP3-positive punctae. ATP and ionomycin were found to cause a BA(\beta)PTA-induced increase in autophagosome formation in HEK cells. Wild type LRRK2, as well as a pathogenic LRRK2 mutant, also stimulated a BA(\beta)PTA-sensitive increase in autophagosomes. The autophagy evoked by LRRK2 was prevented by an antagonist of TPC2 channels. Proposed mechanism: TPC2 → Ca(^{2+}) → CaMKKβ → AMPK → autophagy. The Ca(^{2+})-permeable channel TRPML3 exacerbated autophagy induced by the starvation, tunicamycin and SERCA inhibition in HeLa cells. TRPML3 was localised at the plasma membrane and intracellular vesicles, including autophagosomes, and may provide local Ca(^{2+}) signals required for autophagy. Knock down of TRPML3, or expression of a dominant-negative mutant, reduced autophagy in response to various stimuli. The plant alkaloid evoamide caused a persistent cytosolic Ca(^{2+}) elevation, and induced both apoptosis and autophagy, in glioblastoma cells. The induction of autophagy was inhibited by BAPTA-AM, and was dependent on the activation of c-Jun N-terminal kinases (JNK). Inhibition of T-type voltage-operated Ca(^{2+}) channels (Ca(_3)) was shown to cause cell cycle arrest and death of cancer cells, but was also observed to cause ER stress and inhibition of basal autophagic flux due to reduced Ca(^{2+}) store content.</td>

3. Stimulation of autophagy by Ca\(^{2+}\)

There are numerous examples where imposed, or coincidental, cytosolic Ca\(^{2+}\) signals have activated autophagy ([Table 1](#table1)). Exactly how elevation of cytosolic Ca\(^{2+}\) leads to activation of autophagy is unclear in many situations. Several different Ca\(^{2+}\) sources have been implicated ([69]), along with numerous downstream effectors, including protein kinase C ([38]), Ca\(^{2+}\)/calmodulin-dependent kinase β (CaMKKβ), or CaMKK2) ([70,71]), Ca\(^{2+}\)/calmodulin-dependent kinase [52], ERK [72] and Vps34 (a calmodulin-binding protein) [73]. Of these suggested targets, it is probably fair to say that CaMKKβ has received the most experimental support, whereas the Ca\(^{2+}\) sensitivity of Vps34 is unknown. It was suggested that Vps34 could be activated by Ca\(^{2+}\)/calmodulin [73]. However, Vps34 activity in cellulo was not affected by chelating cytosolic Ca\(^{2+}\), or by a calmodulin antagonist [74]. CaMKKβ is an upstream activator of AMPK [75], and can lead to autophagy through inhibition of mTORC1 ([Fig. 1](#fig1)). Alternatively, AMPK can bypass inhibition of mTORC1 and stimulate autophagy by phosphorylating ULK1 at an activating site [76]. The Ca\(^{2+}\)/CaMKKβ/AMPK signalling pathway has been proposed to underlie increased autophagy in various cell types and experimental conditions, such as cancer cells stimulated with IP3-generating agonists, thapsigargin, ionomycin and a vitamin D analogue [70], neurons in a mouse model of Huntington’s disease, and neuronal cells treated with amyloid-beta peptide [77], and in cells with exogenous LRRK2 expression ([26] ([Table 1])). Consistent with the evidence that an elevated cytosolic Ca\(^{2+}\) concentration stimulates autophagy, there are many reports that showing chelating cytosolic Ca\(^{2+}\) inhibits autophagy ([38,52,70,77–84]). Chelating cytosolic Ca\(^{2+}\) signals is commonly achieved by loading cells with BAPTA-AM ([1,2-bis(O-aminophenoxo)ethane-N\(_2\),N\(_3\),N\(_4\),N\(_4\)‘-tetraacetoyl methyl) ester), a cell-permeable Ca\(^{2+}\)-buffering agent. Loading cells with BAPTA-AM does not just block autophagy in response to experimental manoeuvres that deliberately evoke cytosolic Ca\(^{2+}\) signals, but also in response to starvation, amino acid withdrawal and mTOR inhibition ([53,71,85–87]). Moreover, BAPTA-AM loading typically reduces both the basal number of autophagosomes in cells replete with nutrients, as well as significantly preventing the
formation of new autophagosomes in response to stimulation.

With experiments where cells have been given exogenous stimuli that are expected to evoke cytosolic Ca^{2+} signals (e.g., hormones or thapsigargin), the effect of BAPTA-AM on autophagy could be plausibly explained as a prevention of the stimulus-induced Ca^{2+} increase. However, in those situations where no exogenous stimulus was given to directly cause a cytosolic Ca^{2+} increase (e.g., basal autophagy or rapamycin/nutrient starvation), the inhibitory effect of BAPTA-AM implies that some form of basal or triggered Ca^{2+} signalling is taking place, and that it is essential for both basal autophagic flux and for the on-set of autophagy induced by mTOR inhibition. Exactly when and how such Ca^{2+} signals originate, and which effector(s) are implicated remains unknown, but there are some hints. For example, it has been demonstrated that BAPTA-AM loading of cells (using conditions that blocked autophagy) did not affect the production of PIP3 by Vps34, but altered the accumulation of the PIP3-binding protein WIPI-1 to nascent phagophore membranes [52,59]. In addition, BAPTA-AM was found to prevent endosome/lysosome fusion [88]. These observations suggest that BAPTA-AM does not just block the triggering of autophagy by experimentally-evoked Ca^{2+} signals, but inhibits steps in the formation and processing of autophagosomes.

Whilst the inhibition of autophagy by BAPTA-AM is a consistent observation, there are some issues that need consideration when using Ca^{2+} chelators. For example, buffering ions other than Ca^{2+}, products resulting from hydrolysis of the acetoxymethyl ester, and alteration of Ca^{2+}-dependent cellular signalling processes apart from those directly involved in autophagy, may all lead to unintended outcomes. Moreover, Ca^{2+} chelators such as BAPTA are a finite Ca^{2+} sink when loaded in cells, and can be saturated by persistent Ca^{2+} fluxes. Cells can efficiently extrude Ca^{2+} indicators, especially at 37 °C [89], plausibly via sulfonylpyrazine-sensitive ABC transporters [90], which may also be able to remove BAPTA. These considerations do not mean that Ca^{2+} chelators have no use. Indeed, experiments involving BAPTA have provided some of the strongest evidence for the regulation of autophagy by Ca^{2+}. Rather, the use of chelators needs to be controlled and not over-interpreted. Most studies that have employed chelators such as BAPTA do not actually show changes in specific Ca^{2+} signals, and a process is largely assumed to be Ca^{2+} dependent if BAPTA-AM loading had an effect. A simple control experiment demonstrating that BAPTA-AM loading abrogates Ca^{2+} signals evoked by an IP_3-generating agonist (or acute activation of another Ca^{2+} flux pathway) would illustrate that a Ca^{2+} chelator is loaded/retained inside cells, and is effective in buffering cytosolic Ca^{2+} signals.

Whilst a number of studies have used ionophores and Ca^{2+} ATPase inhibitors to examine the regulation of autophagy by Ca^{2+}, relatively few reports have explored the consequences of Ca^{2+} signals caused by natural agonist stimulation. Purinergic receptors are expressed on the surface many cell types, and are activated by ATP. This nucleotide is released from cells via connexin hemichannels/pannexin channels to support paracrine signalling, and from dying cells wherein it can act as a pro-inflammatory ‘damage-associated molecular pattern’ molecule [91]. ATP has been found to induce autophagy working through both G-protein-coupled P2Y receptors [70,92,93] and ionotropic P2X receptors [94,95]. The consequences of ATP-evoked autophagy are seemingly quite diverse. In hepatocytes, for example, P2X receptor-mediated autophagy enhanced inflammatory signalling [94]. Whereas, with macrophages ATP evoked a rapid P2X-mediated autophagic response due to Ca^{2+} influx that aided in the clearance of mycobacteria from the cells [95]. It has been suggested that the concentration of extracellular ATP may determine autophagic or apoptotic responses in hepatoma cells [96]. The Ca^{2+}-sensing receptor, which is a G-protein-coupled receptor that leads to IP_3 production and Ca^{2+} release, has been shown to mediate increased autophagy in cardiac myocytes undergoing angiotensin II-evoked hypertrophic growth [97].

4. Inhibition of autophagy by Ca^{2+}

Screening of autophagy-inducing molecules identified a number of compounds that suppressed Ca^{2+} signalling, leading to the suggestion that elevation of cytosolic Ca^{2+} inhibited autophagy [57,106]. Specifically, antagonists of voltage-operated Ca^{2+} channels (VOCC), and of IP_3 signalling, were found to enhance autophagy by preventing the activity of Ca^{2+}-sensitive proteases known as calpains. It was suggested that Ca^{2+} signals were necessary for constitutive calpain-mediated cleavage of Atg5, and that the proteolysis of Atg5 prevented induction of autophagy (Atg5 is an essential proximal component of autophagic flux). Blocking calpain-mediated Atg5 proteolysis led to autophagy even in nutrient-rich conditions. These observations indicate that Ca^{2+}-mediated activation of calpain is a key suppressor of autophagic flux, perhaps even more so than other signalling pathways that would be assumed to have principle anti-autophagic roles. Another notable observation from this work was that inhibition of calpain triggered an mTOR-independent autophagic clearance of aggregated proteins in neuronal cells. This evidence suggests that aberrant Ca^{2+} signals in neuronal cells might retard the clearance of aggregation-prone proteins through inhibition of autophagy, thus possibly exacerbating disease conditions. Whilst these studies indicate that calpain can inhibit autophagy, other studies have found that calpain activation is necessary for autophagy [107]. Cytosolic Ca^{2+} signals have also been suggested to inhibit autophagy via activation of mTORC1. For example, knockdown of the lysosomal Ca^{2+} channel TRPML1 (transient receptor potential cation channel, mucolipin subfamily, member 1) was found to prevent mTORC1 activity [108]. The effect of TRPML1 knockdown was reversed by thapsigargin, consistent with mTORC1 being activated downstream of cytosolic Ca^{2+} signals.

Thapsigargin is a convenient experimental tool for generating long lasting cytosolic Ca^{2+} signals, and has been used in many studies of autophagy. Some of the complex effects of thapsigargin on autophagy were mentioned earlier. In many reports, thapsigargin was shown to stimulate autophagy, which would be consistent with a Ca^{2+}-dependent induction of autophagy. However, other studies have shown that treatment of cells with thapsigargin arrested autophagic flux. For example, whilst thapsigargin increased the number of WIPI-1-labelled punctae in cells, consistent with a proximal Ca^{2+}-dependent step leading to activation of autophagy, it prevented both the subsequent development of autophagosomes and the maturation of autophagosomes into autolysosomes (similar results were obtained using A23187 [53]. In another study, thapsigargin did not block autophagosome formation, but it inhibited the fusion of autophagosomes with lysosomes [58] (in this case A23187 did not replicate the effect of thapsigargin). Furthermore, thapsigargin has been shown to inhibit nutrient starvation-induced autophagy [82]. At present, the weight of evidence suggests that thapsigargin may trigger autophagy, but it may also affect autophagic flux at distal steps. Treatment of cells with thapsigargin will cause both an elevated cytosolic Ca^{2+} level and a concomitant loss of ER Ca^{2+} stores. It is therefore plausible that the stimulatory and inhibitory actions of thapsigargin on autophagy are mediated by a balance between cellular responses to elevated cytosolic Ca^{2+} concentration versus loss of Ca^{2+} stores.

Depletion of Ca^{2+} from the ER leads to the activation of a Ca^{2+}-influx mechanism known as store-operated Ca^{2+} entry (SOCE) [109]. This form of Ca^{2+} influx occurs in almost all cell types. Depletion of ER Ca^{2+} stores causes a protein called stromal interaction protein 1 (STIM1), which senses ER luminal Ca^{2+}, to associate with, and activate, ORa Ca^{2+} channels on the plasma membrane [110–114]. SOCE can be essential for the refilling of intracellular Ca^{2+} stores, and for the maintenance of Ca^{2+} signals such as the hormone-evoked repetitive Ca^{2+} oscillations observed in non-excitable cells [115,116]. In colorectal cancer cells, SOCE activates a Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII)/Akt pro-survival signalling pathway, and inhibition of SOCE was found to kill the cells via induction of apoptosis.
Mitochondrial Ca\(^{2+}\) uptake is a critical factor in the regulation of cell death processes [119]. In essence, too little Ca\(^{2+}\) uptake by mitochondria triggers autophagy, whilst too much mitochondrial Ca\(^{2+}\) flux may lead to cell death via apoptosis or necrosis. Here, we will only give a brief overview of mitochondrial Ca\(^{2+}\) signalling linked to autophagy, and direct the interested reader to excellent reviews about the discovery, and regulation, of the mitochondrial Ca\(^{2+}\) uniporter (MCU), as well as mitochondrial Ca\(^{2+}\) homeostasis [120,121].

It has been known since the early 1960s that mitochondria sequester Ca\(^{2+}\) [122,123], but it took many years before the molecules responsible for mitochondrial Ca\(^{2+}\) uptake were identified. An important aspect of mitochondrial Ca\(^{2+}\) signalling is the close apposition of these organelles to ER Ca\(^{2+}\) stores [124,125]. These ER-mitochondria contact sites are termed mitochondria-associated membranes (MAMs) [126,127]. The close proximity of mitochondria and ER means that Ca\(^{2+}\) signals arising from IP₃Rs or ryanodine receptors (RyRs) on the surface of the ER occur adjacent to sites of Ca\(^{2+}\) uptake into the mitochondrion, which involve the voltage-dependent anion channel (VDAC, in the outer mitochondrial membrane) and the MCU complex in the inner mitochondrial membrane [128,129]. The typical distances between mitochondria and the ER in a MAM is ∼10–15 nm and ∼50–100 nm for smooth ER and rough ER, respectively [128,130].

Based on quantification of the sites involved in Ca\(^{2+}\) uptake, 5–20% of mitochondrial surfaces are in close contact with the ER [131], with each contact site being approximately 1 μm² in size [132]. ER stress causes an increase of the number of contact sites and the total length of MAMs [125,133]. MAMs are important for a number of physiological processes; they were first recognised for their involvement in lipid synthesis and for Ca\(^{2+}\) uptake into mitochondria, however, it is now recognised that they are also important for mitochondrial movement and fission, inflammatory responses, apoptosis, and autophagy [129,134,135]. Alteration of MAMs have been linked to a number of disease conditions, including cancer [136,137] and neurodegenerative diseases such as Alzheimer’s, Parkinson’s and amyotrophic lateral sclerosis [126,129,130,134,138,139]. It has been suggested that phagophore membranes can originate at MAMs. Upon starvation, Atg14 moves from a diffuse localisation around the ER membrane into the MAMs. Starvation also recruits Double FYVE-containing protein 1 (DFCP1) and Atg5 to the MAMs, which contribute to autophagosome formation [140].

In many cell types, Ca\(^{2+}\) release from the ER generates global cytosolic Ca\(^{2+}\) signals that peak around 0.5–1 μM [141], but within the small volume of the MAMs, between the ER and outer mitochondrial membrane, the local Ca\(^{2+}\) signal is at least an order of magnitude higher [142]. This Ca\(^{2+}\) concentration is sufficient to activate the MCU despite its relatively low affinity for Ca\(^{2+}\) (Kₐ 20–50 μM) [135]. Ca\(^{2+}\) that accumulates within the mitochondrial matrix is subsequently released via the mitochondrial sodium/Ca\(^{2+}\) exchanger (NCX) and can be taken back up into the ER via SERCA, thus restoring the ER Ca\(^{2+}\) level [143]. This Ca\(^{2+}\) cycling between the ER and mitochondria occurs with cytosolic Ca\(^{2+}\) oscillations during physiological stimulation [144], and may be enhanced by mitochondrial production of reactive oxygen species (ROS), which in turn sensitize the ER Ca\(^{2+}\) release channels [128]. Recently, redox domains at the ER-mitochondrial interface have been identified that are induced and controlled by local Ca\(^{2+}\) signalling between ER and mitochondria [145]. Far from being passive acceptors of Ca\(^{2+}\), mitochondria regulate the generation and characteristics of cellular Ca\(^{2+}\) signals [146–149]. Chronic cytosolic Ca\(^{2+}\) signals, such as those arising from hyperstimulation or cell stress/damage, can lead to exaggerated mitochondrial Ca\(^{2+}\) uptake, and consequent activation of the mitochondrial permeability transition pore, mitochondrial swelling and rupture, followed by release of cytochrome C and other pro-apoptotic factors [135]. Dysfunctional or depolarised mitochondria are removed by mitophagy, the selective degradation of mitochondria by autophagy, to prevent cellular damage [150,151].

Several studies have suggested that Ca\(^{2+}\) uptake by mitochondria is required to prevent AMPK-activated autophagy [152–154], reviewed in [37]. This is due to the fact that the citric acid cycle is stimulated by Ca\(^{2+}\) within the mitochondrial matrix. Specifically, pyruvate dehydrogenase, α-ketoglutarate dehydrogenase and isocitrate dehydrogenase have been shown to be stimulated by Ca\(^{2+}\) within the mitochondrial matrix [155]. Activation of these dehydrogenase enzymes increases the rate of oxidative phosphorylation by boosting the supply of reducing equivalents to the electron transport chain. Moreover, Ca\(^{2+}\) within the mitochondrial matrix has been proposed to increase electron flow through the electron transport chain [156] and enhance the rate of ATP production by the ATP synthase [157,158]. Inhibition of mitochondrial Ca\(^{2+}\) uptake has been suggested to induce a bio-energetic crisis inside cells reminiscent of nutrient starvation, but actually with nutrients present, and in this situation autophagy is activated [152,153,159]. Of particular importance is the transfer of Ca\(^{2+}\) from the ER to mitochondria following activation of IP₃Rs. Inhibiting IP₃Rs using pharmacological reagents (e.g., xestospongin B) [152,153,160], genetic knockdown (e.g., with siRNA [152,153,160]), or preventing production of IP₃ through inhibition of phospholipase C (e.g., with U73122) triggers mTORC1-independent autophagy because of reduced mitochondrial Ca\(^{2+}\) uptake, and consequent reduction of ATP synthase. RyR-mediated Ca\(^{2+}\) release in cardiac myocytes similarly leads to mitochondrial Ca\(^{2+}\) uptake that supports cellular bioenergetics [161].

Given the reported significance of mitochondrial Ca\(^{2+}\) uptake for cellular bioenergetics and cell fate, it is surprising that MCU knockout mice (apart from those on a CD21 background, which are embryonically lethal) are viable and are largely normal. Germ line knockouts have a reduced ability to exercise, an impaired immune function and a lower rate of reproduction, but are viable [162] (the interested reader is directed to reviews that describe the phenotypes of different MCU knockout models [120,121]. Interestingly, no upregulation of autophagy was observed in heart, liver or embryonic fibroblasts isolated from MCU knockout mice [162]. Whereas, reduced expression of MCU in HeLa cells [163] or Trypanosoma brucei [164] does lead to upregulation of autophagy. Also at odds with the notion that inhibition of mitochondrial Ca\(^{2+}\) uptake causes autophagy, it was observed that depolarisation of mitochondria, which would inhibit Ca\(^{2+}\) uptake, did not increase autophagic markers, although ER stress did [160].

6. Inhibition of IP₃R activity triggers autophagy

Evidence indicating that inhibiting transfer of Ca\(^{2+}\) from IP₃Rs to mitochondria triggers autophagy aligns with other observations showing that reduction of IP₃ signalling can be pro-autophagic. For example, incubation of cells with lithium or valproic acid gradually exhausts the cells’ capacity to make IP₃ by inhibiting the recycling of inositol from inositol monophosphates, and the production of newly-synthesised inositol, respectively [165]. Both lithium and valproic acid were found to trigger autophagy in mTORC1-independent manner [57,160], similar to the mTORC1-independent activation of autophagy following direct inhibition of IP₃Rs described above (but see [166] for an mTOR-dependent effect of valproate on autophagy). Expression of IP₃ 3-kinase, which phosphorylates inositol 1,4,5-trisphosphate to inositol 1,3,4,5-tetrasphosphate, increased autophagic clearance of protein aggregates [57]. Diminished IP₃R-mediated Ca\(^{2+}\) signalling
following glucocorticoid treatment of T cells also triggers autophagy [167]. The ER membrane protein Bax inhibitor-1 (Bi-1/TMBIM6), a member of the transmembrane Bax inhibitor motif-containing protein family (TMEM; [168]) with important functions in cell death [169], promotes autophagy by reducing IP$_3$R-mediated Ca$^{2+}$ delivery to the mitochondria [170]. The underlying mechanisms involved Bi-1/TMBIM6’s ability to lower the ER Ca$^{2+}$ store content by forming a Ca$^{2+}$-permeable channel [171,172] and/or directly sensitizing IP$_3$Rs (outside the MAMs) [173]. Restoring normal ER Ca$^{2+}$ loading via SERCA overexpression suppressed Bi-1/TMBIM6-induced autophagy and normalised mitochondrial energetics. Of note, Bi-1/TMBIM6 can also affect autophagy through IRE1α, a branch of the unfolded protein response [174], though this study revealed Bi-1/TMBIM6 as a negative regulator of autophagy. The IP$_3$R antagonist xestospongin B was found to stimulate autophagy in various cell lines, but not in DT40 cells that had a triple knockout of all IP$_3$R isoforms (DT40 TKO; [175]). In breast cancer cells, and a mouse model of breast cancer, the activation of autophagy by inhibition of IP$_3$Rs led to cell death and reduction of tumour growth [176]. We, and others [177], have made similar observations of increased autophagic flux in cells with reduced Ca$^{2+}$ signals by expressing a 3α 5-phosphatase enzyme that efficiently hydrolyses IP$_3$ into IP$_2$ (Fig. 2D), and thereby prevents Ca$^{2+}$ release from IP$_3$Rs without altering IP$_3$R expression or accessory proteins. Removing a chronic inhibition of IP$_3$R-mediated Ca$^{2+}$ release, due to the effects of transglutaminase-dependent IP$_3$R modification, reduced autophagy [178]. These data are all consistent with a necessity for IP$_3$R activity to suppress autophagy.

Whereas the data described above suggest that IP$_3$R-mediated Ca$^{2+}$ release is necessary to prevent the induction of autophagy, several studies have shown that IP$_3$Rs are required for autophagy. For example, incubation of cells with the IP$_3$R antagonist xestospongin B can cause autophagic flux, but when applied to cells under conditions of starvation xestospongin B inhibits autophagy [85]. Moreover, cadmium- and evodiamine-induced autophagy were diminished by the IP$_3$R inhibitor 2-aminoethoxydiphenyl borate (2-APB) [72,104]. IP$_3$Rs associate with Beclin 1, which causes a direct sensitization of IP$_3$R that is necessary to drive the autophagic flux in response to starvation [85]. In addition, the knockout of all three IP$_3$R isoforms in HEK cells [179], which inhibits all agonist-induced Ca$^{2+}$ release [180], prevented autophagy induced by resveratrol [83]. Furthermore, expression of the IP$_3$R-binding domain of IP$_3$Rs (to act as a chelator for IP$_3$) and thereby prevent IP$_3$R activation) inhibited autophagy induced by xestospongin B or nutrient starvation [175], although it is important to note that expression of the IP$_3$R-binding domain will not only inhibit IP$_3$R opening, it will alter the interaction of IP$_3$Rs with autophagic mediators such as Beclin 1 (see below) [177]. Furthermore, IP$_3$Rs were necessary for autophagy triggered by differentiation factor in Dictyostelium discoideum [86]. Intuitively, it would seem reasonable that knockout of IP$_3$Rs might provide a definitive answer as to their role in autophagy. However, this has not been the case as variable outcomes have been reported using IP$_3$R null cells (Table 2). The observations that IP$_3$Rs can be pro- or anti-autophagic are somewhat difficult to reconcile unless IP$_3$Rs, and the Ca$^{2+}$ signals they generate, play alternative roles in different contexts, as previously proposed [181]. For example, an experimental inhibition of IP$_3$ signalling might evoke autophagy by reducing mitochondrial Ca$^{2+}$ uptake and ATP production, as described earlier. In contrast, during chronic starvation, when energy levels are diminishing and autophagy is already activated, IP$_3$R-mediated Ca$^{2+}$ signalling may be pro-autophagic. This is exemplified by the effects of xestospongin B on augmenting autophagy when applied on its own, versus inhibiting starvation-induced autophagy [85].

It has been shown that autophagy can provide a protective support to tumour cells, and this may involve IP$_3$R-mediated Ca$^{2+}$ signalling. For example, in renal cancer cells upregulation of type 1 IP$_3$R promoted the activation of autophagy to support tumour survival [183]. In a different context, inhibiting IP$_3$R-mediated Ca$^{2+}$ release was demonstrated to disproportionately kill tumour cells relative to non-tumorigenic cells [153]. The difference in sensitivity between tumour and non-tumorigenic cells was not due to alterations in their ability to engage autophagy, since autophagy was found to be similarly induced in both types of cell in response to IP$_3$R inhibition. Rather, the reason why IP$_3$R inhibition in cancer cells leads to prominent cell death is that it causes a bioenergetic crisis resulting in failure to complete mitosis, which culminates in necrotic death when tumour cells undergo division [159,184]. The effect of IP$_3$R inhibition could be overcome by incubating cells with a membrane permeant form of pyruvate to stimulate the citric acid cycle, consistent with a metabolic defect downstream of IP$_3$R inhibition due to a decreased rate of mitochondrial respiration. Similarly, inhibiting mitochondrial Ca$^{2+}$ uptake by knockdown of the MCU [153] preferentially led to the death of tumour cells compared to isogenic control cells due to failed cytokinesis.

Cancer cells have a re-modelled metabolism that is often termed the ‘Warburg effect’, wherein they produce ATP via increased glycolysis and reduction of lactic acid, rather than ATP production via oxidation of pyruvate within mitochondria [185]. Beyond increased ATP synthesis, the Warburg effect may promote biosynthetic pathways, impact the tumour environment and enable cell signalling [186]. Indeed, evidence suggests that cancer cells rely on mitochondrial respiration for energy, production of metabolites and anabolic pathways for the synthesis of lipids, DNA and proteins [153,187]. Transfer of Ca$^{2+}$ from IP$_3$Rs to mitochondria therefore sustains the synthesis of essential building blocks for cancer cell survival and cytokinesis. In fact, cancer cells seem addicted to the ER-mitochondrial Ca$^{2+}$ fluxes to fuel mitochondrial metabolism in order to keep up with their uncontrolled proliferation [32,159,184]. In contrast, non-tumorigenic cells slow down their cell cycle in accordance with limitations in mitochondrial metabolism and anabolic pathways so that failed cytokinesis and necrosis do not occur.

Other studies have confirmed the sensitivity of metastatic cancer cells to IP$_3$R inhibition, but in this case involving a contribution of autophagy in the observed cell death. For example, breast cancer cells displayed increased cell death when exposed to the IP$_3$R inhibitors xestospongin C and 2-APB, or following IP$_3$R knockdown, which could be linked to excessive activation of autophagy involving Atg5

---

**Table 2**

Summary of the reported states of autophagy in DT40 cells devoid of IP$_3$R expression.

Knock out of all three IP$_3$R isoforms in DT40 cells (DT40 TKO cells) was observed to increase the basal level of autophagy. Neither rapamycin nor bafilomycin evoked a further increase in autophagic markers. Expression of a pore-dead IP$_3$R mutant did not reduce autophagy levels in the DT40 TKO cells. Bafilomycin did not increase the accumulation of autophagy markers in DT40 TKO cells. The authors concluded that DT40 TKO cells already had achieved the maximum level of autophagic flux. AMPK signalling was not affected in the DT40 TKO cells, but mTORC1 activity was decreased.

The basal level of autophagy was not affected in DT40 TKO cells, and bafilomycin increased the level of autophagy markers. Xestospongin B increased autophagy levels in wild type DT40 cells, but not in DT40 TKO cells. DT40 TKO cells had an increased basal level of autophagy that was further increased by starvation and rapamycin treatment, and decreased by 3-MA (similar to the effect of these compounds in wild type cells). Inhibition of IP$_3$Rs with xestospongin B, preventing IP$_3$ production with U73122, or blocking mitochondrial Ca$^{2+}$ uptake with Ru360 increased autophagy levels in wild type DT40 cells, but not in DT40 TKO cells. Expression of functional RyRs, or a pore-dead IP$_3$R mutant had no effect on the levels of autophagy in DT40 TKO cells.
upregulation [176]. Application of autophagy inhibitors (e.g., bafilomycin or 3-MA), or knockdown of Atg5, suppressed the breast cancer cell death. Irrespective of whether autophagy is involved in cancer cell death processes or not, it is clear that IP₃Rs play a critical role in cancer cell survival [32]. This notion is underpinned by a recent study revealing high IP₃Rs expression in breast cancer patients that could be linked with an increase in metabolic intermediates [176].

7. Ryanodine receptors

Whilst the participation of IP₃Rs in autophagic signalling has been widely studied, less is known about the role of RyRs. Knockout of IP₃Rs stimulated autophagy that could be rescued by re-expression of functional IP₃Rs, but not by channel-dead IP₃Rs or by functional RyRs [152]. Insulin withdrawal leads to cell death via autophagy in the case of neural stem cells [188], potentially as a mechanism for quality control in neuronal differentiation and growth. The effect of insulin withdrawal on autophagic cell death occurred concomitantly with cytosolic Ca²⁺ signals arising from type 3 RyRs, and stimulation of RyR activity augmented cell loss [189]. In neonatal cardiac myocytes type 2 RyRs are substantially more abundantly expressed than IP₃Rs and generate frequent global Ca²⁺ signals [190]. However, inhibition of IP₃Rs was found to trigger autophagy, suggesting that IP₃,R-mediated Ca²⁺ release, but not Ca²⁺ signals arising RyRs, suppresses autophagy [43]. In contrast to the observations in neonatal myocytes, the reduced expression of type 2 RyRs in adult cardiac myocytes led to decreased mitochondrial metabolism and increased autophagy [161], similar to the effect of reduced IP₃R expression that was discussed above [152]. HEK cells heterologously expressing type 3 RyRs are useful experimental tools to study unprovoked cellular Ca²⁺ signals since they show frequent spontaneous Ca²⁺ release events [191]. Such expression of type 3 RyRs in HEK cells blocked autophagic flux, whereas pharmacological inhibition of endogenous RyRs in differentiated C2C12 cells or in primary rat hippocampal neurons, or of ectopically expressed RyRs in HEK293 cells, augmented autophagic flux [192]. It was suggested that RyR-mediated Ca²⁺ release suppressed autophagic flux by preventing autophagosome-lysosomal turnover. This latter study nicely illustrates the importance of monitoring autophagic flux, rather than looking at accumulation of LC3-II, to establish how a particular experimental intervention is impacting autophagy.

8. Remodelling of Ca²⁺ signalling and involvement of Bcl-2 family members in Ca²⁺-dependent autophagy

Cellular Ca²⁺ signalling may be remodelled during conditions that lead to autophagy [181]. During starvation, the Ca²⁺ content of the intracellular stores was increased, the Ca²⁺ leak rate from the ER decreased and IP₃Rs became more sensitive to IP₃ [85]. Similar changes occurred following inhibition of mTOR by rapamycin [87]. These changes in Ca²⁺ signalling did not appear to be a consequence of ongoing autophagy, since remodelling induced by either rapamycin [87] or nutrient starvation [193] was observed in Atg5 null cells in which autophagy did not occur. Rather, the sensitisation of IP₃Rs could be linked to an increased binding of Beclin 1 to IP₃Rs in starved cells. Moreover, the starvation-induced sensitization of IP₃Rs was abrogated in Beclin 1-deficient cells, but not in Atg5-deficient cells (Atg5 functions downstream of Beclin 1). IP₃ sensitization occurring during starvation was dependent on Beclin 1, since Beclin 1 knockdown prevented the enhancement of IP₃,R-mediated Ca²⁺ release in starved cells, but did not affect Ca²⁺ release in non-starved cells. In addition, recombinantly-expressed, purified Beclin 1 was able to directly sensitize IP₃,R-mediated Ca²⁺ release in permeabilised cells. Beclin 1 was found to bind to the amino-terminal IP₃-binding domain of IP₃Rs, where it can exert significant allosteric control of IP₃ activity [85]. Potentially at odds with this sensitisation of IP₃,R-mediated Ca²⁺ release during autophagy, it has also been demonstrated that IP₃Rs can physically interact with, and are phosphorylated by, mTOR, thereby causing increased Ca²⁺ release when autophagy may actually be least active [194,195].

The expression of wide type Bcl-2, or ER-targeted Bcl-2, inhibited autophagy evoked by a number of Ca²⁺-mobilising stimuli [70,175]. However, whereas Bcl-2 expression inhibited autophagy evoked by starvation, lithium and xestospongin B, it did not affect that caused by tunicamycin or thapsigargin [160]. It has been suggested that Bcl-2 blocks autophagy by reducing ER Ca²⁺ content [82], but reduction of ER Ca²⁺ content by Bcl-2 is not universally observed [195,196]. It therefore seems more likely that Bcl-2 (and other anti-apoptotic Bcl-2 family members) inhibit autophagy by scaffolding and neutralizing Beclin via its BH3 domain [197]. Indeed, it is well known that Beclin-1/Bcl-2 interaction blocks autophagy [197,198]. Moreover, knockdown of Beclin-1 via siRNA inhibited autophagy evoked by Ca²⁺-mobilising stimuli [70]. The Bcl-2/Beclin 1 expression ratio may be a determinant of how cells die (i.e. whether by apoptosis or autophagy). In prostate cancer cells, when given a BH3 mimetic compound to disrupt the Bcl-2/Beclin 1 interaction, a relatively low Bcl-2 expression makes cells more prone to apoptosis, whereas a high Bcl-2 expression leads to autophagy [198].

It is likely that IP₃Rs have a role in scaffolding both Beclin 1 and Bcl-2, thereby increasing their proximity and enhancing their anti-autophagic interaction [199]. However, the precise details of the Beclin 1/Bcl-2/IP₃R interaction are unclear. The association of Beclin 1 with the amino-terminal IP₃-binding domain of IP₃Rs has been reported in independent studies [85,175], but a sensitisation of IP₃,R-mediated Ca²⁺ release due to Beclin 1 binding has not been consistently observed. It is plausible that the Beclin 1/Bcl-2/IP₃R interaction is disengaged as a pro-autophagic event. For example, Beclin 1 can be phosphorylated by the Ca²⁺/calmodulin-activated kinase called death-associated protein kinase (DAPK), thereby releasing it from Bcl-2 and triggering autophagy [200]. Likewise, Bcl-2 can be phosphorylated by JNK, for example downstream of ER stress, which will also liberate Beclin 1 [201]. Moreover, xestospongin B, at a concentration that triggered autophagy, altered the interaction of Beclin 1 and IP₃Rs, consistent with a mechanism in which Beclin 1 is released from Bcl-2/IP₃Rs to induce autophagy [175], but this has also not been consistently observed [152]. Of note, Beclin 1-mediated sensitization of IP₃Rs was independent of Bcl-2 interaction, since a Beclin 1 F123A mutant, which lacks Bcl-2-binding properties, remained capable of IP₃R sensitization [85]. In contrast to wild-type Beclin 1, the Beclin 1 F123A mutant failed to form complexes with IP₃Rs in either non-starved cells or in cells undergoing starvation. These observations support a model where Beclin 1 might be dependent on Bcl-2 to be targeted to the ER, where it would be in the proximity of IP₃Rs, but is released from Bcl-2 upon starvation (or downstream of cellular signalling processes), thereby being available to enhance IP₃,R-mediated Ca²⁺ release and influence autophagy.

9. Lysosomes as a dynamic Ca²⁺ store

Apart from their importance for cellular recycling processes, lysosomes have become increasingly recognised as a significant intracellular Ca²⁺ store. The luminal Ca²⁺ concentration within a lysosome is estimated to be ~200–500 μM [202,203] and is thus somewhat lower than that typically found in the ER [141]. Moreover, the volume of lysosomes inside a cell is less than that of the ER [204], and consequently the total amount of Ca²⁺ available to be released from the lysosomal Ca²⁺ store is smaller than that from the ER. However, Ca²⁺ release from lysosomes has been shown to be important for several cellular processes, such as endo-lysosomal trafficking events [203,205], skeletal muscle differentiation in mice and zebrafish [206–208], neurite extension [209], fertilisation [210–213], plasma membrane currents and insulin secretion in pancreatic β-cells [214,215] and Ebola virus infection [216,217] (reviewed in [218]).

Ca²⁺ can be released from lysosomes and lysosome-like organelles
by nicotinic acid adenine dinucleotide phosphate (NAADP). The Ca\textsuperscript{2+}-
releasing potential of NAADP was first shown using sea urchin egg homogenates [219], and it was later established that NAADP acts as a Ca\textsuperscript{2+}-
releasing intracellular messenger on an organelle that was dis-
tinct from the ER [220,221]. A physiological role for NAADP-mediated Ca\textsuperscript{2+}
signalling has now be confirmed for many organisms, including vertebrate systems (reviewed in [218]). Given that lysosomes have a lesser capacity for Ca\textsuperscript{2+} storage than the ER, it is not surprising that
NAADP evokes relatively modest cytosolic Ca\textsuperscript{2+} signals. However, the Ca\textsuperscript{2+} released by NAADP can be amplified by Ca\textsuperscript{2+}-
induced Ca\textsuperscript{2+} release (CICR) from nearby IP\textsubscript{3}Rs and RyRs [215,222]. As with MAMs, lysosomes have been found to form close contact sites with the ER/SR. An electron microscopy study showed that the majority (~82%) of lysosomes in human fibroblasts are < 20 nm from the ER [223]. Simi-
larly, in COS-7 cells lysosomes are present in close proximity to IP\textsubscript{3}Rs on the ER [224].

The Ca\textsuperscript{2+} transfer between the ER and lysosomes is bidirectional [225]. Not only does Ca\textsuperscript{2+} released from lysosomes trigger CICR from the ER, Ca\textsuperscript{2+} released from the ER is taken up into acidic organelles. Such a bidirectional Ca\textsuperscript{2+} transfer has the potential to shape intra-
cellular Ca\textsuperscript{2+} oscillations, and shows similarities to the ER-mi-
tochondria interaction described earlier [141,226]. Whilst there is an intimate connection between lysosomes and the ER, Ca\textsuperscript{2+} entry via SOCE in non-excitable cells [224], or via VOCCs in cardiac myocytes [227], seems to have a lesser effect on lysosomal Ca\textsuperscript{2+} signalling. However, by exploiting transcription factor EB (TFEB)-induced lyso-
osomal biogenesis [228], it was shown that lysosomes present near the cell membrane can modulate SOCE by buffering cytosolic Ca\textsuperscript{2+} levels, thereby reducing ER reuptake of Ca\textsuperscript{2+} [229].

10. Lysosomal Ca\textsuperscript{2+} release channels

The main candidates for lysosomal Ca\textsuperscript{2+} release channels are TRPM2 (transient receptor potential cation channel subfamily M member 2), TRPML1 and two-pore channels (TPCs). TRPM2 is mostly localised at the plasma membrane, and inhibits autophagy via CaMKII-
dependent phosphorylation of Beclin 1 (which increases Beclin 1:Bcl-2 localised at the plasma membrane, and inhibits autophagy via CaMKII-
member 2), TRPML1 and two-pore channels (TPCs). TRPM2 is mostly
activated by NAADP [231]. However, the NAADP concentration needed
for many organisms, including

\textbf{11. TPC-interacting proteins}

A mass spectrometry study found that TPC1 and TPC2 interact with
several proteins known to be important for cellular Ca\textsuperscript{2+} homeostasis (e.g., Ca\textsuperscript{2+}-binding proteins like annexins and calreticulin, STIM- and
IP\textsubscript{3}R-interacting proteins), and with trafficking regulators (e.g., Rab
GTPases, syntaxins, sigma receptors) [240]. TPCs also interact with autophagy regulators (e.g., nonaspanins and the amino acid antiporter
SLC7A5-SLC3A2). TPCs co-immunoprecipitate with mTOR [240–242],
and it has been proposed that mTOR binds to TPCs under nutrient-rich conditions and inhibits channel opening. Whereas, a decline in cellular
ATP concentration releases mTOR from TPCs, thereby promoting Ca\textsuperscript{2+}
release. mTOR kinase activity is crucial for this effect. However, there is
debate about whether mTOR acts upstream of TPCs, as shown in
myoblasts [242], or downstream of TPCs, as shown for macrophages
[241]. TPCs have also been shown to interact with LRRK2, which can
trigger autophagy [26]. TPCs, and NAADP-induced Ca\textsuperscript{2+} release, can increase both apoptosis and autophagy in cells overexpressing LRRK2
[26,243].

\textbf{12. TPCs and autophagy}

Ca\textsuperscript{2+} is known to be important for vesicular fusion events, such as
those occurring during autophagy [203,205], and it is likely that lys-
osomes contribute to such Ca\textsuperscript{2+} signals. Moreover, Ca\textsuperscript{2+} release from
receptors [243,244], and BOX-1R-interacting proteins), and with trafficking regulators (e.g., Rab
GTPases, syntaxins, sigma receptors) [240]. TPCs also interact with autophagy regulators (e.g., nonaspanins and the amino acid antiporter
SLC7A5-SLC3A2). TPCs co-immunoprecipitate with mTOR [240–242],
and it has been proposed that mTOR binds to TPCs under nutrient-rich
conditions and inhibits channel opening. Whereas, a decline in cellular
ATP concentration releases mTOR from TPCs, thereby promoting Ca\textsuperscript{2+}
release. mTOR kinase activity is crucial for this effect. However, there is
debate about whether mTOR acts upstream of TPCs, as shown in
myoblasts [242], or downstream of TPCs, as shown for macrophages
[241]. TPCs have also been shown to interact with LRRK2, which can
trigger autophagy [26]. TPCs, and NAADP-induced Ca\textsuperscript{2+} release, can increase both apoptosis and autophagy in cells overexpressing LRRK2
[26,243].

\textbf{12. TPCs and autophagy}

Ca\textsuperscript{2+} is known to be important for vesicular fusion events, such as
those occurring during autophagy [203,205], and it is likely that ly-
osomes contribute to such Ca\textsuperscript{2+} signals. Moreover, Ca\textsuperscript{2+} release from
to be sensitive to NAADP [241]. However, the NAADP concentration needed
to activate the TRPM2 is much higher than that typically reported for
the NAADP-induced Ca\textsuperscript{2+} release inside cells, making it unclear whe-
ther TRPM2 is physiologically activated by NAADP [204]. TRPML1 was the
first Ca\textsuperscript{2+} channel identified on lysosomes [232], and was reported
to be sensitive to NAADP [233,234], but these findings could not be
confirmed in over-expression or knockdown studies [235]. TRPML1 can
conduct currents of various cations, including Ca\textsuperscript{2+}. TRPML1 may
putatively release Ca\textsuperscript{2+} from lysosomes, but its regulation by NAADP
remains unclear [141,204]. Over-expression of TRPML1 has been shown to increase autophagy, and TRPML1 silencing reduced the level
of autophagy in HeLa cells. These effects appear to be mediated by
Ca\textsuperscript{2+}/calcinulin-dependent translocation of the transcription factor
TFEB to the nucleus, driving the expression of genes underlying au-

taphagic flux and lysosomal biogenesis [102,236]. In addition, release of
lyosomal Ca\textsuperscript{2+} through TRPML1 was found to activate mTORC1
[108]. TPCs are localised on endo-lysosomal organelles and show many
of the hallmark properties of being bona fide NAADP receptors [215,237]. However, NAADP does not seem to bind directly to TPCs
[238,239]. Three TPC isoforms have been cloned, and have potentially
distinct distributions and functions. TPC1 and TPC3 are expressed on
endosomes, whereas TPC2 is present on lysosomes [205].

\begin{table}[h]
\centering
\caption{Effects of NAADP signalling and TPCs on autophagy in various cell types.}
\begin{tabular}{|l|l|}
\hline
Effect & Referenced Methodology \\
\hline
NAADP, which was inhibited by Ned-19. NAADP prevented dynemin-dependent organelle movement, so that autophagosomes and lysosomes did not meet and fuse. & [244] \\
\hline
Using mouse coronary arterial myocytes, the authors found an increase in autophagosome accumulation following activation of lysosomal Ca\textsuperscript{2+} release by
NAADP, which was inhibited by Ned-19. NAADP prevented dynemin-dependent organelle movement, so that autophagosomes and lysosomes did not meet and fuse. & [243] \\
\hline
Using primary astrocytes, the authors found an increase in autophagy following TPC over-expression, or stimulating cells with NAADP-AM. These effects
were sensitive to 3-MA and Ned-19. & [245] \\
\hline
The authors demonstrated a blockade of autophagic flux in TPC over-expressing HeLa cells that was further increased by stimulation with NAADP-AM. TPC over-expression alkalinised the lysosomal pH (4.9 vs. 5.2); re-acidifying lysosomes removed the blockade of the autophagic flux and reduced the
level of autophagy. The TPC2 effects were bafilomycin-insensitive, but sensitive to Ned-19 and BAPTA-AM. Expression of a pore-dead TPC2 mutant did not affect autophagic flux. & [246], but see [247] \\
\hline
In the same study as above, the authors used mouse ES cells and showed that autophagy was increased during neural differentiation. Over-expression of
TPC2 in the ES cells also increased the number of autophagosomes by inhibiting autophagic flux (i.e., it was bafilomycin insensitive). Downregulation of TPC2 via shRNA reduced the accumulation of autophagosomes, which resulted from an increased autophagic flux. The effects of TPC2 on
autophagic flux were mediated via the alkalinisation of lysosomes, and were rapamycin insensitive. & [246] \\
\hline
\end{tabular}
\end{table}
Table 3). TPC knockout mice generated in different laboratories vary considerably in their phenotypes, and whether or not functional TPCs are knocked out is still a matter of debate (discussed in [251]). In addition, the effects of TPC knockdown can vary between cells and tissues. Macrophages from TPC1/2 double knockout mice show no gross alterations in autophagy (basal or starvation-induced). Although, TPCs seemed to be important for the efflux of amino acids from lysosomes under low ATP conditions, which in turn can affect the intracellular nutritional status and autophagy [241]. In contrast, a higher level of autophagic flux following starvation was observed in skeletal muscle from TPC2 knockout mice [242].

13. Summary

Whilst it is presently difficult to reconcile all of the substantial literature concerning the regulation of autophagy by Ca2+, there are some consensual themes emerging. For example, a bulk of evidence suggests that imposition of cytosolic Ca2+ signals by a variety of means, and from different sources, can trigger autophagy. However, it is also apparent that in some contexts Ca2+ co-exist could be very informative about the characteristics of Ca2+ signals mediating these discrete outcomes. Presumably, some differences in the kinetics, amplitude or spatial extent of cytosolic Ca2+ signals determine a pro- or anti-autophagic fate. With regard to stimulation of autophagy by Ca2+, a few signalling moieties have been consistently implicated, including CaMKKβ, CaMKII, AMPK, Akt and PKC. In particular, the activation of AMPK downstream of CaMKII has been reported in a number of studies. Perhaps the most consistent observation of all is that loading cells with intracellular Ca2+ signals impact on autophagic degradation: thrown over balance in neurodegenerative disease, Cell Calcium 47 (2010) 112–121.
