Abstract. Atmospheric pCO$_2$ is a critical component of the global carbon system and is considered to be the major control of Earth’s past, present, and future climate. Accurate and precise reconstructions of its concentration through geological time are therefore crucial to our understanding of the Earth system. Ice core records document pCO$_2$ for the past 800 kyr, but at no point during this interval were CO$_2$ levels higher than today. Interpretation of older pCO$_2$ has been hampered by discrepancies between proxy methods used to reconstruct pCO$_2$: the carbon isotope fractionation that occurs during photosynthesis in haptophyte biomarkers (alkenones) and the boron isotope composition ($\delta^{11}$B) of foraminifer shells. Here, we present alkenone and $\delta^{11}$B-based pCO$_2$ reconstructions generated from the same samples from the Pliocene and across a Pleistocene glacial–interglacial cycle at Ocean Drilling Program (ODP) Site 999. We find a muted response to pCO$_2$ in the alkenone record compared to contemporaneous ice core and $\delta^{11}$B records, suggesting caution in interpreting alkenone-based reconstructions of pCO$_2$.

1 Introduction

Understanding the absolute level and evolution of atmospheric pCO$_2$ through geological time is essential to our understanding of the Earth’s climate system. As both a fundamental first-order control and a contributor to multiple dynamic feedbacks, atmospheric pCO$_2$ is critical in setting Earth’s surface temperature (Lacis et al., 2010). Reconstructing pCO$_2$ evolution improves our understanding of both the mechanisms behind past climate change (Chalk et al., 2017) and provides novel constraints on climate sensitivities (PALAEOSENS, 2012; Martínez-Boti et al., 2015). This then allows ground truthing of our understanding the climate and the Earth system models that are used for predicting future climate change.

Over the past two decades, two common marine-based CO$_2$ proxies have emerged – alkenone-based $\varepsilon_p$ values (CO$_2p_{\text{alk}}$), utilizing the carbon isotopic fractionation imparted during photosynthesis in a subgroup of haptophytes
(Bidigare et al., 1997), and planktic foraminiferal δ11B values (CO2(δ11Bplank)), based on the pH control of boron speciation and isotopic fractionation in seawater (Hemming and Hanson, 1992). Multiple records of atmospheric pCO2 now exist for the Cenozoic from both methods, showing a broadly similar long-term trend from a high-CO2 greenhouse world of the early Cenozoic, when CO2 exceeded 400µatm and may have been higher than 1000µatm, to a low-CO2 bipolar glaciated world of the Late Pleistocene, when CO2 fell to below 300µatm (Pagani et al., 2005; 2011; Pearson et al., 2009; Anagnostou et al., 2016; Foster et al., 2017; Sosdian et al., 2018; Super et al., 2018).

However, discrepancies have recently become apparent between both methods when applied to the last 20 Ma (Badger et al., 2013a, b). Specifically, the CO2(εalg−alk) reconstructions often suggest a lower magnitude of short-term pCO2 change compared to that from CO2(δ11Bplank) (Badger et al., 2013b). Whilst this could be partially explained by mismatches between the sampling intervals, or by the influence of local surface water disequilibrium with the atmosphere with respect to CO2, this discrepancy remains even for records generated from exactly the same sediment samples (Badger et al., 2013b vs. Martínez-Botí et al., 2015). Both the CO2(εalg−alk) and CO2(δ11Bplank) have been used to estimate Earth system sensitivity in the Pliocene with differing results, with CO2(εalg−alk) suggesting a higher-than-present Earth system sensitivity Pliocene (7–10°C per CO2 doubling; Pagani et al., 2009), whilst CO2(δ11Bplank) records sensitivity in line with our estimates for today (<5°C per CO2 doubling; Martínez-Botí et al., 2015). Although this is at least partly due to the different approaches used to calculate Earth system sensitivity in the two studies, it is also due to the differences in reconstructed pCO2 from the two approaches.

The CO2(εalg−alk) and CO2(δ11Bplank) palaeobarometers are both based on mechanistic frameworks that have been calibrated in either the modern ocean or laboratory culture (Bidigare et al., 1997; Hemming and Hanson, 1992; Sanyal and Hemming, 1996; Pagani et al., 2002). These proxies can be further ground truthed in the recent geological past, when ice core records provide high-quality pCO2 data for the last 800 kyr (Bereiter et al., 2015 and Table 1). In previous work, both CO2(δ11Bplank) (Sanyal et al., 1995; Hönisch and Hemming, 2005; Foster, 2008; Henehan et al., 2013; Foster and Sexton, 2014; Chalk et al., 2017) and CO2(εalg−alk) (Jasper and Hayes, 1990) have yielded pCO2 records similar in absolute value and amplitude of change to those derived from ice cores. However, the emerging discrepancies between the two methods (Badger et al., 2013a, b; Martínez-Botí et al., 2015) necessitate revisiting this validation, both between the two proxies and between marine proxy and ice core reconstructions.

The ice cores record the pCO2 of the Pleistocene glacial–interglacial cycles (Bereiter et al., 2015 and Table 1) and provide an opportunity for cross-calibrating proxy methods for determining atmospheric pCO2 in the geological archive (CO2(εalg−alk) and CO2(δ11Bplank)) with the direct-CO2 measurements from the ice cores.

### Study site

Ocean Drilling Program (ODP) Site 999 is located in the Caribbean Sea (12°44.639′N, 78°44.360′W; 2838 m water depth; Fig. 1), has an orbitally calibrated age model, and has been used previously for CO2 reconstructions. Our temporal sampling resolution is ~6 kyr in the Pleistocene and ~9 kyr in the Pliocene. Although CO2(εalg−alk) and CO2(δ11Bplank) are independent of one another in many respects, they both rely on assumptions about the equilibrium of surface seawater with the atmosphere with respect to CO2, sea surface temperature, and on well-constrained age models, which can make direct comparison between records from different sites difficult. Here, we overcome these problems by producing CO2(εalg−alk) and CO2(δ11Bplank) records from identical horizons in the same deep-ocean sediment core in (1) the late Pleistocene, permitting direct comparison to ice core data (Figs. 2a, 3), and (2) across the intensification of Northern Hemisphere glaciation (INHG) in the Pliocene (Seki et al., 2010; Martínez-Botí et al., 2015) (Fig. 2b).

In terms of CO2, ODP Site 999 in the Caribbean Sea is today slightly out of equilibrium with the atmosphere, with surface waters a little oversaturated in CO2, providing a small net source of CO2 to the atmosphere (~21 µatm; Takahashi et al., 2009). However, the site has been shown to be suitable for recording past changes in pCO2 (Foster, 2008; Foster and Sexton, 2014) and the air–sea equilibrium is not thought to have changed significantly from the Pliocene to today (see discussion in Bartoli et al., 2011). It is one of few sites where both alkenone and boron isotope records can be acquired given the good preservation of both foraminifera and organic matter (Foster, 2008; Badger et al., 2013b; Foster and Sexton, 2014; Martínez-Botí et al., 2015), and Pliocene records of both are available (Bartoli et al., 2011; Badger et al., 2013b; Martínez-Botí et al., 2015). It also has been demonstrated previously to record glacial–interglacial cycles of pH / CO2 (Foster, 2008; Henehan et al., 2013) and a Pleistocene CO2(δ11Bplank) record from 0 to 250 ka has been recently published (Chalk et al., 2017).

### 2 Methods

#### 2.1 Alkenone isotopes

Our new alkenone-based CO2 record was calculated following Badger et al. (2013b), with modern-day phosphate used in the estimation of the “b” term, U2O4′/2′′, temperatures, and modern-day salinity (35 psu). Samples were freeze dried, ground to a fine powder by hand, and extracted by Soxhlet apparatus using a dichloromethane (DCM) / methanol azo trope (2 : 1, v/v) refluxing for 24 h. Total lipid extracts were divided into three fractions (F) by small (4 cm) sil-

Figure 1. Site map with locations of sites discussed in the text.

Alkenone identification was confirmed by gas chromatography (GC) mass spectrometry (ThermoQuest Trace MS, He carrier gas). Alkenone isotope analyses were performed using a Thermo Fisher Delta V connected via a GC isolink and ConFlo IV to a Trace GC. The GC oven was programmed to increase in temperature from 70 to 200 °C at 20 °C min\(^{-1}\), then to 300 °C at 6 °C min\(^{-1}\) and held isothermal for 25 min. Conversion to Vienna Pee Dee Belemnite (VPDB) was performed by reference to a laboratory standard gas of known \(\delta^{13}C\) and system performance was monitored using in-house fatty acid methyl ester and \(n\)-alkane standard mixtures of known isotopic composition. Long-term precision is approximately 0.3 ‰. To estimate sea surface temperature (SST), the \(F_2\) fraction was also analysed by GC-flame ionization detection (Hewlett Packard 5890 Series II), and the GC oven was programmed to increase in temperature from 70 to 130 °C at 20 °C min\(^{-1}\), then to 300 °C at 4 °C min\(^{-1}\) and held isothermal for 25 min. An approximately 50 m, 0.32 mm internal diameter capillary column with a 0.12 µm thick dimethylpolysiloxane equivalent film. A \(H_2\) carrier gas was used, and quantification was monitored using a hexadecan-2-ol standard added prior to column chromatography. System performance as monitored with an in-house fatty acid methyl ester standard. Alkenone ratios were converted to SST using the global core-top calibration of Müller et al. (1998). Although this is a linear calibration, our uncertainty treatment (see below) should encompass any minor deviation from linear as \(U'_{K37}\) approaches 1 (see also the discussion in Badger et al., 2013b). All alkenone analyses were carried out at the Bristol node of the NERC Life Sciences Mass Spectrometry Facility hosted by the Organic Geochemistry Unit, University of Bristol.

The alkenone isotope \(\delta^{13}C\) value is used to calculate the total carbon isotope fractionation that occurs during algal growth (\(\epsilon_p\)). This isotopic fractionation has been shown to be controlled by [CO\(_2\)\(_{aq}\)] (Eq. 1; Jasper and Hayes, 1990) which can then be converted to atmospheric CO\(_2\) using Henry’s law.

\[
\epsilon_p = \epsilon_f - \frac{b}{[CO_2(aq)]}
\]  

To calculate \(\epsilon_p\) from alkenone \(\delta^{13}C\) values, the carbon isotopic composition of dissolved inorganic carbon (DIC) is required; this is calculated from planktic foraminiferal calcite \(\delta^{13}C\), whilst the fractionation which occurs during carbon fixation (\(\epsilon_f\)) is assumed constant here. The \(b\) term is the sum of other physiological factors (such as growth rate, cell size, and light limitation) which is estimated from the relationship shown in the modern ocean between \(b\) and dissolved reactive phosphate [PO\(_4^{3-}\)] . Further details of the treatment are detailed in Badger et al. (2013b).

Error bars in relevant figures are all 1 SD and based on a full Monte Carlo propagation (\(n = 10000\)) of the following...
uncertainties: $\pm 2^\circ C$ and $\pm 0.1 \%_e$ were applied to temperature and foraminiferal calcite $\delta^{13}C$ (normal probability function (pdf); $2\sigma$ error) and $\pm 2$ and $\pm 0.1$ to salinity and $[PO_4^{3-}]$, respectively ($2\sigma$; uniform pdf). Uncertainties on alkenone $\delta^{13}C$ were estimated from replicate runs and calcite $\delta^{13}C$ from repeat runs of an internal standard. Integrated analytical and calibration uncertainties for alkenone-based temperatures were estimated and conservative estimates of likely variation for salinity and $[PO_4^{3-}]$ were used. An 11\% error on the slope of $b = a[PO_4^{3-}]+c$ was assumed, where $a = 116.96$ and $c = 81.41$ (Paganî et al., 1999).

For consistency with the $CO_2(\delta^{11}B_{plank})$ record for this site, we now adjust for the disequilibrium by subtracting the present-day $CO_2$ surplus and thus recalculate the included values of Badger et al. (2013b) accordingly. SSTs for our new Pliocene data were published in Davis et al. (2013).

### 2.2 Boron isotopes

Boron isotope data were published in Chalk et al. (2017) and are from the same core samples as our alkenone measurements. *Globigerinoides ruber sensu stricto* (white, $n \sim 200$ individuals from 300 to 355 µm) samples were measured for boron isotope composition on Thermo Scientific Neptune multicollector inductively coupled plasma mass spectrometer (MC-ICP-MS) at the University of Southampton according to methods described elsewhere (Rae et al., 2011; Foster et al., 2013; Martínez-Botí et al., 2015). Analytical uncertainty is given by the external reproducibility of repeat analyses of Japanese Geological Survey Porites coral standard (JCP) at the University of Southampton following Henehan et al. (2013) and is typically $0.2 \%_e$ (at 95\% confidence). Metal element to calcium ratios (Li, Mg, B, Na, Al, Mn, Ba, Sr, Cd, U, Nd, and Fe) were analysed using an Thermo Element 2XR ICP-MS at the University of Southampton.
Figure 3. New and recalculated data for CO\(_2(\varepsilon_p-\text{alk})\) for the Pleistocene and Pliocene from ODP Site 999. Alkenone \(\delta^{13}C\) values are shown as red circles for the Pleistocene (a) and Pliocene (b), with \(G.\ ruber\ \delta^{13}C\) from the same samples shown in blue. Alkenone unsaturation-derived SST is shown for the Pleistocene (b) and Pliocene (f). The Pliocene SST data have been previously published in Davis et al. (2013) and are from the same samples as our alkenone \(\delta^{13}C\) values. Calculated \(\varepsilon_p\) data are for the Pleistocene (c) and Pliocene (g) and atmospheric \(p\text{CO}_2\) from CO\(_2(\varepsilon_p-\text{alk})\) for the Pleistocene (d) and Pliocene (h) (red diamonds). Ice core \(p\text{CO}_2\) data are shown for the Pleistocene (black circles) for comparison (Bereiter et al., 2015 and Table 1).

Southampton). Here, these data are used to assess adequacy of clay removal (Al / Ca < 100 \(\mu\text{mol} \text{ mol}^{-1}\)) and to generate down core temperature. pH and CO\(_2\) were calculated using a Monte Carlo approach (uncertainties are 2 SD, \(n = 10\ 000\) replicates) using R (R Core Team, 2015). For pH, we use a boron isotopic composition of seawater of 39.6 ‰ (2 SD of 0.1; Foster et al., 2010) and experimentally determined isotopic fractionation factor (1.027; Klochko et al., 2006), as well as the species-specific calibration for \(G.\ ruber\) of Henehan et al. (2013) (also with incorporated uncertainties). For the CO\(_2\) calculations, we use a range of salinity (equal to that used in the CO\(_2(\varepsilon_p-\text{alk})\) calculations) and total alkalinity.
(TA) that encompasses the modern values (34–37 and 2100–2500 μM, respectively, both with a uniform rather than normal probability distribution. Temperature was determined using Mg/Ca of G. ruber following established methods; DeLannay and Boyle, 1985; Evans and Müller, 2012). Mg/Ca SST of planktic foraminifera is used for \( CO_2(\delta^{13}B^{\text{plank}}) \) and alkenone \( U^{\text{K}}_S \) for \( CO_2(\delta^{13}p-\text{alk}) \) so that the carrier organisms for the \( CO_2 \) reconstruction and SST measurements match, ensuring the temperature measurement is coming from the appropriate part of the water column. Inorganic chemical constants were used from the seacarb package in R (Gattuso, 2018) appropriate part of the water column. Inorganic chemical constants were used from the seacarb package in R (Gattuso, 2018) and alkenones \( pK_B^* \) (dissociation constant for boric acid) (Dickson, 1990). Reconstructed atmospheric \( CO_2 \) values from Foster (2008) were recalculated to match this approach. All uncertainties are included in our simulation and are roughly equivalent to those assumed for the alkenone data and are exactly the same as those used for Martínez-Botí et al. (2015), excluding the \( \delta^{13}B_{\text{sw}} \), thus providing a fair comparison.

### 2.3 Coccolith length measurements

The uptake of \( CO_2 \) into the coccolithophore cell is affected by the cell size and geometry; using alkenones limits the variation of cell geometry by restricting the source organism to one with exclusively spherical cells (Laws et al., 1997; Popp et al., 1998), but some change in cell size is possible. Coccolith size is used as an semi-quantitative proxy for cell size because coccolith size is typically larger on larger cells, with that relationship being broadly consistent within a single taxonomic group where growth behaviour is broadly comparable (Henderiks, 2008; Gibbs et al., 2013; Sheward et al., 2017). Long-axis coccolith length measurements were therefore taken from 100 specimens of the family Noelaerhabdaceae per sample from standard smear slides. Specimens were imaged at 1500× magnification and measured using CellID software.

To investigate the potential influence of changing cell size on \( CO_2(\delta^{13}p-\text{alk}) \), Eq. (1) can be adapted:

\[
\delta_p = \delta_f - \frac{b'}{[CO_2(\text{aq})]}.
\]  

with \( b' \) calculated from using the volume to surface area ratio (\( V:SA \)) of modern and fossil coccospheres (Eq. 3; Henderiks and Pagani, 2007):

\[
b' = \frac{V : SA_{\text{fossil}}}{V : SA_{\text{Ehux}}}.
\]  

\( V : SA_{\text{Ehux}} \) is 0.9 ± 0.1 μm in modern haptophytes (Popp et al., 1998) and \( V : SA_{\text{fossil}} \) can be estimated from lith size measurements (Eq. 4; Henderiks and Pagani, 2007):

\[
D_{\text{cell}} = 0.55 + 0.88L_{\text{coccolith}}.
\]

### 2.4 Age model

For the 0–500 ka interval, we generated a detailed age model by tuning the planktic foraminifer (G. ruber) \( \delta^{18}O \) record from Site 999 (at ~ 0.5 to 2.0 kyr resolution) (Schmidt et al., 2006) to the LR04 benthic \( \delta^{18}O \) stack (Lisiecki and Raymo, 2005) using the AnalySeries software (Paillard et al., 1996). The Pliocene portion of Site 999 is part the LR04 stack and that astronomically tuned age model is used here (Lisiecki and Raymo, 2005).

### 2.5 Bayesian exploration of \( CO_2(\delta^{13}p-\text{alk}) \) input variables

In order to examine the influence of the various input parameters for the calculation of \( pCO_2 \) from alkenone \( \delta^{13}C \) values, we carry out a second set of Monte Carlo simulations \((n = 100\,000)\) with expanded uncertainty. In this case, we more fully explore uncertainty space using the following input uncertainties (at 95 % confidence or full range): SST (normal distribution, ±6°C), \( \varepsilon_f \) (uniform distribution, 24 to 28), \( b \) (normal distribution, ±40), and \( CO_2 \) disequilibrium (20±20). These input distributions are our prior distributions. We then evaluate the \( CO_2 \) output for each alkenone sample against synchronous ice core \( pCO_2 \) and boron isotope \( pCO_2 \) for the Pleistocene and Pliocene, respectively. By only selecting those simulated alkenone \( pCO_2 \) levels that agree with ice core or \( pCO_2(\delta^{13}B^{\text{plank}}) \) (including associated uncertainties), we can reevaluate the input distributions (our posterior) and gain insights into the relative importance of each of the input variables in potentially driving the observed disagreement in \( pCO_2 \). Uncertainties in the \( pCO_2(\delta^{13}B^{\text{plank}}) \) are as described above, and we apply an uncertainty of ±6 ppm (2 s) for the ice core \( pCO_2 \) record (Ahn et al., 2012).

### 3 Results and discussion

Alkenone and G. ruber \( \delta^{13}C \) values (Fig. 3a, e) were used to calculate \( \varepsilon_p \) values (Fig. 3c, g). Alkenone \( \delta^{13}C \) values are relatively stable through the Pleistocene portion of the record, varying between −24.5‰ and −23.2‰. Values are slightly higher in the Pliocene, varying between −24.1‰ and −21.7‰. G. ruber \( \delta^{13}C \) values are relatively stable through the whole record, varying between 0.53‰ and 1.57‰. These give rise to \( \varepsilon_p \) values which are similarly fairly stable, varying between 10.5‰ and 12.2‰ in the Pleistocene, and between 9.53‰ and 11.8‰ in the Pliocene. Our \( U^{\text{K}}_S \) SST (Fig. 3c, g) record shows warmer temperatures in the Pliocene of around 27°C, with cooler temperatures recorded in the Pleistocene, with the coldest SST recorded in the glacial which is ~2°C cooler than the interglacial. These records are combined (see methods section) to produce the \( pCO_2 \) record (Figs. 2, 3c, f), which shows largely stable and invariant values through both the Pliocene and Pleistocene portions of our record.
Published low temporal resolution Pliocene records from Site 999 (Seki et al., 2010), using both the CO$_2$(δ$_{13}$Bplank) and CO$_2$(ε$_p$−alk) palaeobarometers, show a pCO$_2$ decrease at ∼2.8 Ma. However, this agreement relies on correcting the CO$_2$(ε$_p$−alk) for changes in haptophyte cell size, which was based on a low temporal resolution lith size record (Seki et al., 2010). Changes in haptophyte cell size alter the volume to surface area ratio available for gaseous exchange and can therefore modify the fractionation recorded by CO$_2$(ε$_p$−alk) (Popp et al., 1998). Our new CO$_2$(ε$_p$−alk) record at Site 999 now spans 3.3–2.6 Ma at higher temporal resolution, supplementing data from Badger et al. (2013b). A lith size record has also been generated for the same samples used for CO$_2$(ε$_p$−alk) for 3.3–2.6 Ma (Davis et al., 2013). We find no evidence to support the change in lith size applied by Seki et al. (2010) with lith size (and hence cell size) remaining stable across the primary pCO$_2$ change at 2.8 Ma (Davis et al., 2013). Consequently, although our new CO$_2$(ε$_p$−alk) record is of higher resolution than that of Seki et al. (2010), we no longer have any evidence for the cell size shift at 2.7 Ma (Fig. 4).

We compare our record with the CO$_2$(δ$_{13}$Bplank) records of Martínez-Botí et al. (2015) in Fig. 2. With the cell size correction now removed, the decrease in CO$_2$(ε$_p$−alk) across the
INHG, and the agreement of CO$_2$(ε$_p$–alk) with CO$_2$(δ$_{13}$B$_{\text{plank}}$), both now disappear (red symbols, Fig. 2b). As such, CO$_2$(ε$_p$–alk) for this whole Pliocene interval (2.6–3.3 Ma) remains stable and low (mean CO$_2$(ε$_p$–alk) = 251 ± 13; 1σ min = 228, max = 286 µatm), whereas CO$_2$(δ$_{13}$B$_{\text{plank}}$) is on average higher and more variable (mean CO$_2$(δ$_{13}$B$_{\text{plank}}$) = 342 ± 50; 1σ min = 234, max = 452 µatm).

In the Pleistocene, our CO$_2$(ε$_p$–alk) record covers one complete glacial–interglacial (G-IG) cycle from 110 to 260 ka, encompassing MIS5–7, and the end of MIS8, and terminations II and III (open red diamonds; Fig. 2a). The CO$_2$(δ$_{13}$B$_{\text{plank}}$) record of Chalk et al. (2017) covers two G-IG cycles from the late Holocene to MIS8 (open blue circles; Fig. 2a). δ$_{13}$B$_{\text{plank}}$ closely tracks the rise and fall of pCO$_2$ derived from ice cores (Chalk et al., 2017), with CO$_2$(δ$_{13}$B$_{\text{plank}}$) exhibiting similar values to atmospheric CO$_2$ within uncertainty (Fig. 2a), and with only small deviations from ice core CO$_2$ as a result of (i) the noise in the reconstruction and (ii) perhaps a small diagenetic effect on CO$_2$(δ$_{13}$B$_{\text{plank}}$) relating to periods of carbonate dissolution in portions of the core which show high foraminiferal fragmentation (e.g., MISS5d; Schmidt et al., 2006).

In contrast, CO$_2$(ε$_p$–alk) is within error of the ice core data only during the interglacials when CO$_2$ partial pressures are similar to those of the pre-industrial era. Crucially, CO$_2$(ε$_p$–alk) clearly fails to record the lower pCO$_2$ of the glacial periods, remaining at around 260 µatm throughout (mean CO$_2$(ε$_p$–alk) = 259 ± 27; Fig. 2a). This concentration of pCO$_2$ is also very close to that recorded by CO$_2$(ε$_p$–alk) in the Pliocene at this site (mean CO$_2$(ε$_p$–alk) = 252 ± 26 µatm; Fig. 2). Similar alkenone behaviour has also been observed in another, albeit lower-resolution, record from ODP Site 925 (Zhang et al., 2013; Fig. 2), where the CO$_2$(ε$_p$–alk) remains unchanged during the Pleistocene (20–170 ka) and Pliocene.

Overall, these results suggest that, at least at these sites, the CO$_2$(δ$_{13}$B$_{\text{plank}}$) Palaeobometer does faithfully record atmospheric CO$_2$ change, whereas the CO$_2$(ε$_p$–alk) proxy is unable to reconstruct the low levels of atmospheric CO$_2$ during the glacial. This suggests that, in its present and frequently applied form, CO$_2$(ε$_p$–alk) is not accurately recording atmospheric CO$_2$ and this could explain the discrepancy between the Pliocene CO$_2$(ε$_p$–alk) and CO$_2$(δ$_{13}$B$_{\text{plank}}$) records. We further evaluate this by using regression analysis between ice core and the paired-proxy data (Fig. 5). CO$_2$(δ$_{13}$B$_{\text{plank}}$) levels are largely consistent with those determined from ice cores, clustering around the 1 : 1 line with a slope also close to 1 (0.95 ± 0.13) (Fig. 5a), whereas variance in CO$_2$(ε$_p$–alk) is strongly muted compared to that observed in the ice core data (Fig. 5b).

As both cell size (Popp et al., 1998) and growth rate (Bidigare et al., 1997) can modify δ$_{13}$C$_{\text{alk}}$ via the b term, we investigated whether either of these could explain the muted response of CO$_2$(ε$_p$–alk) to atmospheric CO$_2$. Haptophyte cell size can be estimated from their lith size, but as noted above, there is no evidence for significant changes in the

![Figure 5. Regression analyses of proxy-based pCO$_2$ with ice core data (a) CO$_2$(δ$_{13}$B$_{\text{plank}}$) (Chalk et al., 2017) and (b) CO$_2$(ε$_p$–alk) vs. ice core data (Bereiter et al., 2015 and Table 1) for MIS5–8, interpolated in the age domain. Regression lines (in red/blue) are linear fits with 68% and 95% confidence intervals, calculated by bootstrapping the uncertainties in proxy pCO$_2$ (Monte Carlo method described in the methods section). Uncertainty in the ice core values is by estimated by applying a 3000 uncertainty in the age model during interpolation. Uncertainty envelopes considering data points alone (no bootstrap) are solid lines, with $p_{\text{max}}$ regressions in the thicker, darker colours. A 1 : 1 line is shown in grey for comparison. Statistical calculations were performed in R (R Core Team, 2015).

Pliocene (Davis et al., 2013) nor is there evidence for any change across MIS5–8 (Fig. 4a). There is an overall reduction in mean lith size from the Pliocene to the Pleistocene (Fig. 4a, b), which could offset a long-term pCO$_2$ decline and thus explain the apparent lack of difference between Pliocene and Pleistocene CO$_2$(ε$_p$–alk) at Site 999 (Fig. 6). However, this longer-term reduction in lith size cannot explain the muted response to Pleistocene G-IG CO$_2$ change.

Growth rate is more difficult to reconstruct; most available proxy systems reconstruct phytoplankton or whole ecosys-
Figure 6. Cell size corrections to CO$_2$(\(\varepsilon_p-\text{alk}\)). Ornamentation is the same as Fig. 1, with the addition of cell-size-corrected CO$_2$(\(\varepsilon_p-\text{alk}\)). The smaller liths than modern E. huxleyii across all of our records mean that a direct application of the method of Henderiks and Pagani (2007) results in substantially lower CO$_2$(\(\varepsilon_p-\text{alk}\)) throughout (open orange stars; c, d). As the main interest is in the effect of the Plio-Pleistocene change in cell size we observe, we adjusted the \(b'\) term so that CO$_2$(\(\varepsilon_p-\text{alk}\)) matched our uncorrected CO$_2$(\(\varepsilon_p-\text{alk}\)) record during the last interglacial (filled orange stars; a, b).

The failure of CO$_2$(\(\varepsilon_p-\text{alk}\)) from these two sites to record the G-IG CO$_2$ variation also necessitates reassessment of earlier CO$_2$(\(\varepsilon_p-\text{alk}\)) studies that were able to reconstruct such changes. For instance, whilst Jasper and Hayes (1990) replicated the CO$_2$ change over the last 100 kyr of the Vostok ice core from Deep Sea Drilling Project (DSDP) Site 619 (Gulf of Mexico) and Bae et al. (2015) are able to replicate the ice core data at a site in the Sea of Japan, records from the Arabian Sea (Palmer et al., 2010), Angola Current (Andersen et al., 1999), and the equatorial Atlantic (Zhang et al., 2013) either fail to record ice core CO$_2$ or require additional corrections to do so (Fig. 7). It may also be that at some sites, such as at equatorial Pacific MANOP (Manganese Nodule Project) site C (Figs. 1, 7), these records represent changing air–sea disequilibrium (Jasper et al., 1994). Two of these studies interpreted their data using a different \(\varepsilon_p\) relationship than later work; when these data are recalculated using the more recent model, the patterns remain unchanged (Fig. 7). What is more, in a global alkenone \(\delta^{13}C\) calibration study (Pagani et al., 2002) aimed at replicating Holocene atmospheric conditions, it was noted that low-latitude (sub-tropical) sites perform poorly, consistent with our observations. Considering this present study and previously published work, five out of seven late Pleistocene alkenone \(\delta^{13}C\)
Figure 7. Recalculated $\text{CO}_2(\varepsilon_{\text{p}}-\text{alk})$. Previous work (Jasper and Hayes, 1990; Jasper et al., 1994) calculated $\text{CO}_2(\varepsilon_{\text{p}}-\text{alk})$ using a different model; here, we recalculate the earlier work using the modern methodology and Monte Carlo propagation applied to our other sites. All previous records have been recalculated using the same methodology as our new record, with some corrections and adjustments (for example, for growth rate or lith size) removed to allow direct comparisons. Records are from MANOP site C from the central equatorial Pacific (0°57.2' N, 138°57.3' W; filled green circles; Jasper et al., 1994), DSDP Site 619 in the Pigmy Basin, northern Gulf of Mexico (27°11.6' N, 91°24.5' W; open green circles; Jasper and Hayes, 1990), site OSPC-21 from the Sea of Japan (38.40° N, 131.55° E; open blue triangles; Bae et al., 2015), site NIOP464 in the Arabian Sea (22.15° N, 63.35° E; open orange hexagons; Palmer et al., 2010), site GeoB 1016-3 in the Angola Current (11.59° S, 11.70° E; inverted purple triangles; Andersen et al., 1999), and ODP Site 925 (4°12.25' N, 43°29.33' W, open dark red squares; Zhang et al., 2013). Ice core data are shown as filled black circles and lines (Bereiter et al., 2015 and Table 1). Dashed lines are $2\sigma$ uncertainties from Monte Carlo error propagation as described elsewhere in the text.

As noted above, mean lith size is significantly different for the Pliocene and Pleistocene. A comparison of our posterior $b$ and lith size does reveal a good correlation between these variables (Fig. 11; $r^2 = 0.52$, $p \ll 0.01$), though this is largely, but not exclusively, a function of the mean change.
across the Plio-Pleistocene. Importantly, the observed relationship between \( b \) and lith size is very different from that described in Henderiks and Pagani (2007), suggesting that if lith size is important, our understanding, at least as laid out in Henderiks and Pagani (2007), is incorrect.

An alternative explanation however could be that the parameterization of physiological factors into the \( b \) term model is simply flawed in general, or is at least lacking important components. The dominant species producing alkenones in this part of the Caribbean today is *Emiliania huxleyi* (Winter et al., 2002). *E. huxleyi* first appeared 290 kyr ago but did not become the dominant Noelaerhabdaceae until \( \sim 82 \) ka, when it began to outcompete the closely related *Gephyrocapsa* spp., which in turn took over from *Reticulofenestra* in the late Pliocene (Raffi et al., 2006; Gradstein et al., 2012). Both our alkenone records are therefore a composite of closely related but distinct Noelaerhabdaceae species, with neither record dominated by *E. huxleyi*. We cannot rule out that there could be physiological differences between the extant *E. huxleyi* species and the alkenone producers for our record. However, the Site 925 \( \mathrm{CO}_2(\varepsilon_p - \text{alk}) \) record of the last glacial–interglacial cycle, which would have pri-
Figure 10. Relationships between CO$_2$ and (a) the $b$ term, (b) $\varepsilon_f$ and (c) SST. In each panel, the median of each posterior distribution is shown in red for the Pliocene and blue for the Pleistocene. Note that the CO$_2$ for each data point is either from the ice core or CO$_2(\delta^{11}B_{\text{plank}})$ for the Pleistocene and Pliocene, respectively. The linear patterns that emerge here essentially represent the relationships of the Bidigare et al. (1997) approach given our otherwise invariant $\varepsilon_p$.

Emerging insights into coccolithophore CO$_2$ allocation pathways and their sensitivity to CO$_2$ and temperature, in contrast to the $\varepsilon_p$ values being relatively stable across G-IG cycles. The $\varepsilon_p$ values may instead be due to problems with CO$_2(\varepsilon_p-\text{alk})$.

4 Conclusions

Our data show that the classical application of the alkenone $p$CO$_2$ proxy fails to capture glacial–interglacial changes observed in the ice cores. With increased confidence in CO$_2(\delta^{11}B_{\text{plank}})$ supplied by that proxy’s ability to capture Pleistocene $p$CO$_2$ variability, our data also suggest that the discrepancy between CO$_2(\delta^{11}B_{\text{plank}})$ and CO$_2(\varepsilon_p-\text{alk})$ in the Pliocene may also be due to problems with CO$_2(\varepsilon_p-\text{alk})$. Emerging insights into coccolithophore CO$_2$ allocation pathways and their sensitivity to CO$_2$ and temperature, in contrast to the $\varepsilon_p$ values being relatively stable across G-IG cycles. The $\varepsilon_p$ values may instead be due to problems with CO$_2(\varepsilon_p-\text{alk})$. Emerging insights into coccolithophore CO$_2$ allocation pathways and their sensitivity to CO$_2$ and temperature, in contrast to the $\varepsilon_p$ values being relatively stable across G-IG cycles. The $\varepsilon_p$ values may instead be due to problems with CO$_2(\varepsilon_p-\text{alk})$. Emerging insights into coccolithophore CO$_2$ allocation pathways and their sensitivity to CO$_2$ and temperature, in contrast to the $\varepsilon_p$ values being relatively stable across G-IG cycles. junction with our inter-proxy comparisons, indicate that the long-standing CO\(_2\)\(_{\text{alk}}\) proxy requires major revision and recalibration. If CCMs are preferentially more important for the alkenone palaeobarometer than growth rate, the muted alkenone palaeobarometer response may be limited to the low-CO\(_2\) world of the Plio-Pleistocene and particularly in tropical waters where CO\(_2\)\(_{\text{aq}}\) is especially low. By extension, this proxy (and interpretations based on it) likely retains utility at higher CO\(_2\) levels typical of the early Cenozoic (and at high latitudes where CO\(_2\)\(_{\text{aq}}\) is high) where active carbon uptake is less likely (Zhang et al., 2013). Regardless, the discrepancy between CO\(_2\)\(_{\delta^{13}C}\) and ice core CO\(_2\) records indicates that alkenone isotopes in several locations do not faithfully record atmospheric CO\(_2\) at relatively low, Plio-Pleistocene-like CO\(_2\) levels. Furthermore, the muted response of CO\(_2\)\(_{\delta^{13}C}\) to CO\(_2\)\(_{\text{aq}}\) at lower concentrations calls into question the underlying basis of the high climate sensitivities previously reconstructed using this method in the Plio-Pleistocene (Pagani et al., 2009). This, coupled with further evidence of the fidelity of CO\(_2\)\(_{\delta^{11}B}\) at Site 999, suggests that the climate sensitivities derived from CO\(_2\)\(_{\delta^{11}B}\) (which are consistent with climate models used both in palaeoclimate and future climate projections) are more accurate (Martínez-Boit et al., 2015).

**Data availability.** Data are archived on Pangaea (https://doi.pangaea.de/10.1594/PANGAEA.899353) (Badger et al., 2019).

**Supplement.** The supplement related to this article is available online at: https://doi.org/10.5194/cp-15-539-2019-supplement.

**Author contributions.** MPSB and GLF conceived the study (conceptualization). MPSB, TBC, and GLF designed the methodology, carried out data collection, and analysed the data (formal analysis, investigation, methodology). PRB, SIG, HP, and AM performed data collection. PFS finalized the age model (investigation). MPSB wrote the manuscript and prepared figures (visualisation, writing – original draft). RDP (PI), GLF, and DNS (Cols) supervised the project and acquired funding (funding acquisition and supervision). All authors contributed to interpretation, writing, and reviewing the manuscript (writing – review and editing).

**Competing interests.** The authors declare that they have no conflict of interest.

**Acknowledgements.** This study used samples provided by the International Ocean Discovery Program (IODP). We thank Alex Hull and Gemma Bowler for laboratory work, Lisa Schönborn and Günter Meyer for technical assistance, Alison Kuhl and Ian Bull for research support, and Andy Milton at the University of Southampton for maintaining some of the mass spectrometers used in this study. This study was funded by NERC grant NE/H006273/1 to Richard D. Pancost, Daniela N. Schmidt and Gavin L. Foster (which supported Marcus P. S. Badger). We also acknowledge the ERC Award T-GRES and a Royal Society Wolfson Research Merit Award to Richard D. Pancost. Gavin L. Foster is also supported by a Royal Society Wolfson Research Merit Award. We thank Kirsty Edgar for comments on an early draft of the manuscript, the two anonymous reviewers of this submission, and reviewers through various rounds of review whose comments greatly improved the manuscript. We are grateful to Thomas Bauska for encouraging us to do better at referencing the ice core data, and John Jasper for discussion of the early days of the alkenone palaeobarometer.

**Review statement.** This paper was edited by Luc Beaufort and reviewed by two anonymous referees.
