Summary

- Neotropical peatlands emit large amounts of methane (CH4) from the soil surface, but fluxes from tree stems in these ecosystems are unknown. In this study we investigated CH4 emissions from five tree species in two forest types common to neotropical lowland peatlands in Panama.
- Methane from tree stems accounted for up to 30% of net ecosystem CH4 emissions. Peak CH4 fluxes were greater during the wet season when the water table was high and temperatures were lower. Emissions were greatest from the hardwood tree Campnosperma panamensis, but most species acted as emitters, with emissions declining exponentially with height along the stem for all species.
- Overall, species identity, stem diameter, water level, soil temperature and soil CH4 fluxes explained 54% of the variance in stem CH4 emissions from individual trees. On the landscape level, the high emissions from C. panamensis forests resulted in that they emitted at 340 kg CH4 d−1 during flooded periods despite their substantially lower areal cover.
- We conclude that emission from tree stems is an important emission pathway for CH4 flux from Neotropical peatlands, and that these emissions vary strongly with season and forest type.

Introduction

Wetlands are the largest natural source of atmospheric methane (CH4) (Houghton et al., 1994; Ciais et al., 2013), contributing 17–40% of global emissions (Laanbroek, 2010; IPCC 2013). Two-thirds of the global CH4 emissions from wetlands are estimated to come from undisturbed tropical wetlands (Melton et al., 2013). Of the total area of wetlands in the tropics (1386 000 km²), peatlands represent 32%, located mainly in the lowland humid forests of Southeast Asia, Amazonia, Central America and equatorial Africa (Page et al., 2011; Sjögersten et al., 2014; Dargie et al., 2017; Leifeld and Menichetti 2018). Given the large area of tropical peatlands and their capacity for high CH4 emissions, at least in the Neotropics (Sjögersten et al., 2014; Teh et al., 2017; Winton et al., 2017; Hoyos-Santillan et al., 2019), tropical peatlands may be important components in the global CH4 cycle. Furthermore, these ecosystems are vulnerable to human disturbances with direct implications for atmospheric greenhouse gas concentrations (Couwenberg et al., 2010; Page et al., 2011; Lähteenoja et al., 2012; Sjögersten et al., 2014; Leifeld and Menichetti 2018).

Recent evidence points towards trees as an underestimated contributor to wetland CH4 emissions and a major pathway for the egress of soil-produced CH4 (Terazawa et al., 2007; Gauci et al., 2010; Rice et al., 2010; Pangala et al., 2013, 2015, 2017; Terazawa et al., 2015; Covey & Memonigal, 2019; Jefferies et al., 2019). This appears to be particularly important in tropical wetlands, because CH4 emissions from seasonally flooded wetlands on mineral soils are responsible for half of all CH4 emissions from mineral soils within the Amazon basin (Pangala et al., 2017). For a tropical forested peatland in Southeast Asia, in the only study so far to report CH4 emissions from trees in tropical peatlands (Pangala et al., 2013), tree stems were found to emit substantially more CH4 than peat surfaces, accounting for 62–87% of the total ecosystem CH4 emissions.

Methane production and subsequent emissions from wetland soils are controlled by a number of abiotic and biotic factors linked to the degree of water logging, temperature, substrate availability and microbial community composition (Jauhainen et al., 2005; Wright et al., 2011; Hoyos-Santillan et al., 2016; Sjögersten et al., 2018; Girkin et al., 2018). Vegetation alters all of these factors, either directly or indirectly. Specifically, the vegetation alters microtopography and peat structure, which affects the water table; shading from the canopy, which controls air temperature; and through litter quality and root exudates, which affects substrate availability (Hoyos-Santillan et al., 2016; Baird...
et al., 2017; Girkin et al., 2018). In some areas, methane fluxes are controlled by seasonal variation in rainfall (Teh et al., 2017), but such impacts depend on the strength of seasonality. Indeed, work in the Bocas del Toro region, Panama, indicates no clear differences in CH$_4$ emissions between seasons, despite water table being a strong predictor of emissions (Wright et al., 2011; Hoyos-Santillan et al., 2019).

The magnitude of emissions from trees has been related to tree age, height, density of lenticels, and the concentration of CH$_4$ in the soils (Pangala et al., 2013, 2015, 2017; Covey & Megonigal, 2019; Welch et al., 2019). Tree species differ in their physiology, so the composition of the tree community might also influence tree methane emissions (Pangala et al., 2013, 2017). In Neotropical peatlands, peat surfaces emit variable quantities of CH$_4$, with persistently high soil emissions in some forest types (e.g. Wright et al., 2011; Hoyos-Santillan et al., 2016, 2019; Teh et al., 2017; Winton et al., 2017). However, the role of the trees as mediators of soil-produced CH$_4$ emissions in such peatland systems is unknown.

Consequently, as high soil CH$_4$ emissions have been recorded in Neotropical peatlands, and data on CH$_4$ emissions from trees in peatlands in the Neotropics is lacking, we aimed to understand whether trees are large contributors to net ecosystem emissions in neotropical peatlands, and if so to determine the drivers of tree CH$_4$ emissions. To address this knowledge gap we formulated the following hypotheses. Tree emissions are an important contributor to net CH$_4$ emissions from tropical peatlands, in line with findings from Southeast Asian peatlands and mineral soil wetland systems (Pangala et al., 2017). Tree species, and hence forest species composition, affect the magnitude of tree emissions. To test these hypotheses we measured the contribution of trees to ecosystem CH$_4$ emissions in two common hardwood forest types of a well-studied neotropical lowland peatland in Central America (Panama) using soil and stem sampling chambers coupled to an optical methane analyser along four transects. After examining how the specific stem emissions evolved with stem sampling positions above the forest floor of up to 5 m, we explored how these emissions were influenced by species and by extensions the type of forest stand (mixed or mono-dominant) and the fluctuations of the water table over contrasting periods of wetness. Finally, land cover mapping allowed us to scale the tree emissions to the two target vegetation types across the whole wetland extent. We focused the study on Central America as it hosts an important number of lowland peatlands (Lawson et al., 2014), some of which are well described with regard to vegetation communities and soil CH$_4$ emissions (Phillips et al., 1997; Sjøgersten et al., 2011; Wright et al., 2011; Hoyos-Santillan et al., 2016).

Materials and Methods

Study site

The study site was in the San San Pond Sak wetland (site 611, rsis.ramsar.org) in the Bocas del Toro Province in the northwestern Caribbean region of Panama (Fig. 1). This wetland covers 164 km$^2$ with a range of vegetation types: mangroves, shallow, brackish and freshwater lakes, and peatlands. It includes the 80 km$^2$ Changuinola peat deposit, an ombrotrophic peatland within which seven distinct phasic plant communities have been identified (Phillips et al., 1997). These communities are palm forest, mixed forest, hardwood forest, stunted forest and open bog plain vegetation covering large areas.

The nearby town of Bocas del Toro, Isla Colon (c. 10 km) has a mean annual temperature of 26.4$^\circ$C (mean min. 26.3$^\circ$C and mean max 30.3$^\circ$C) and an annual precipitation average of 3397 mm (Smithsonian Tropical Research Institute physical monitoring programme 2003–2015). The climate is equatorial and there is no distinct dry season. Nevertheless, the meteorological year is divided into four parts: two periods of lower rainfall approximately from mid-December to the end of May (266 mm per month) and August to October (217 mm per month), and two wetter periods between June and July (329 mm per month) and November to December (403 mm per month) (STRI physical monitoring programme 2004–2015).

Fig. 1 Study site location in Bocas del Toro, Panama, showing extent of the San San Pond Sak wetland overlaid on 2014 RapidEye imagery, and field transects overlaid on 2014 Google Earth imagery.
We conducted the study in two common phasic communities, mixed forest and *Campnosperma panamensis* forest (Phillips *et al*., 1997), along four independent transects at which both of the forest types occurred (i.e. *n*= 4). The transects were placed on either side of a small inlet into Bahia Almirante to ensure spatial independence (c. 900 m apart) (Fig. 1).

We used visual interpretation of very high-resolution RGB satellite imagery from Google Earth to identify four transects, which included transitions between our two target vegetation types within a relatively short distance (400–600 m). All study sites were freshwater, and further details of the biogeochemical and hydrological properties of the sites can be found elsewhere (Baird *et al*., 2017; Sjögersten *et al*., 2018). At the selected location field data collection was carried out between July 2013 and January 2015.

**Vegetation survey**

Along each transect, within each of the target phasic communities we delimited 400 m² plots (this resulted in eight plots in total, i.e. four mixed forest and four *Campnosperma* forest). We subsequently made a vegetation survey of the plots, measuring diameter at breast height for all stems > 3 m in height and identifying them to species based on Phillips *et al*. (1997), the database created by STRI for the Bocas del Toro region (http://biogeodb.stri.si.edu) and a digital herbarium from the University of Costa Rica (http://hergol.biologia.ucr.ac.cr).

**Stem-flux measurements**

Stem CH₄ fluxes were measured from *C. panamensis* (Anacardiaceae), *Casipourea eliptica* (Rhizophoraceae), *Symphonia globulifera* (Clusiaceae), *Prioria copaifera* (Fabaceae), *Pithecolobium* sp. (Fabaceae) and *Euterpe precatoria* (Palmaceae), which were common species in the study area. The trees selected for measurement were representative of the range of size of mature trees of each species. All species display adaptation to wetland conditions with features such as prop roots, lenticels and aerencyma formation to enable oxygen transport to the root system.

To determine the relationship between stem height and stem CH₄ emissions and if this varied between species, we measured the stem emissions of the five most abundant hard wood tree species up to 5 m height, *n*= 4 for each species. Measurements were made at 35, 75, 115, 200, 300, 400 and 500 cm. As *E. precatoria* is a small palm it was not possible to measure this species at 400 and 500 cm, and therefore it was not included at this stage.

Tree-stem CH₄ emissions were measured using semi-rigid stem chambers (Siegenthaler *et al*., 2016). The air temperature and air humidity of each chamber was recorded with small dataloggers (ST-171, Clas Ohlson, Insjön, Sweden). The chambers were covered with a plasticised aluminium foil to maintain adiabatic chamber conditions.

The stem chambers were connected to an ultra-Portable greenhouse gas analyser (UGGA, Los Gatos Research Inc., Mountain View, CA, USA) via two 4.6 m long and 5 mm inside diameter polytetrafluoroethylene-coated polyvinyl chloride parallel tubes (Nalgene, Rochester, MN, USA) set in a continuous flow mode operating as a closed loop with a flow of 2–4 l min⁻¹. The UGGA measured CH₄ with off-axis integrated cavity output spectroscopy (OA-ICOS) at a frequency of 0.33 Hz. Gas concentrations were then measured for 5 min. The analyser’s uncertainty in the range of 0.01 to 100 ppmv methane is < 1% without calibration and the precision is ± 0.6 ppb over a period of 100 s (Los Gatos Research, 2013).

The rates were calculated from linear regressions made between the concentration changes starting after an equilibration period of 90 s and the elapsed runtime. After accounting for the chamber volume, which varied between measurements depending on the required chamber size (the range of chamber size was 0.28–1.49 dm³ and 95–715 cm² for volume and area, respectively), rates were then expressed relative to the exchange surface area.

The ambient fluxes were corrected to reference fluxes using the following transformation:

\[
F_{\text{ref}} = F_{\text{amb}} \frac{P_{\text{amb}}}{P_{\text{ref}}} \times \frac{T_{\text{ref}}}{T_{\text{amb}}} 
\]

Eqn 1

where \(F_{\text{ref}}\) = flux corrected to reference conditions, \(F_{\text{amb}}\) = flux measured at ambient conditions, \(P_{\text{amb}}\) = atmospheric pressure at ambient conditions, \(P_{\text{ref}}\) = pressure at reference conditions (1 atm), \(T_{\text{ref}}\) = temperature at reference conditions (298 K) and \(T_{\text{amb}}\) = temperature at ambient conditions (°K).

To find the best-fit lines going through the seven heights we regressed stem CH₄ fluxes as a function of height (\(F_{\text{CH}_4(h)}\)) and the stem radius as a function of height (\(r(h)\)). To test if we could predict the fluxes up to 5 m height by only using the first three heights we regressed \(F_{\text{CH}_4(h)}\) and \(r(h)\) with a reduced number of points; for \(F_{\text{CH}_4(h)}\) three heights (35, 75 and 115 cm) and for \(r(h)\) four heights (35, 75, 115 and 200 cm) as the stem circumference were easily measurable up to 200 cm. From the best-fitted functions established on these first few points we determined which functions best predicted overall emissions up to 5 m high by comparing predicted values with observed emissions.

**Upscaling stem emissions into tree emissions**

To determine the tree stem fluxes for the two forest types we measured stem methane fluxes from all trees in each plot between August–October 2013 (a drier period) and November 2014–January 2015 (a wetter period). A total of 297 trees were measured over these two periods, 245 and 52 in the first and second period, respectively. Measurements were balanced between the two vegetation types within each of the two periods. We calculated the stem emissions for a whole tree using \(F_{\text{CH}_4(h)}\) and \(r(h)\). The infinitesimal methane emission (\(dF\)) from an infinitesimal height \(dh\) could be expressed as:

\[
dF = 2\pi f(h) r(h) dh
\]

Eqn 2
To calculate the emissions over height range we integrated Eqn 4 over the height going from zero to a certain maximal height \( H \). This is done by determining the anti-derivative \( f(h) \) and \( r(h) \) functions:
\[
F = 2\pi \int_0^H f(h) r(h) dh = F(0) - F(H) \quad \text{Eqn 3}
\]

The two functions that suited all tree species were exponential functions \( f(h) = ab^h \) and \( r(h) = cd^h \). Eqn 4 was reformulated with the anti-derivative of the two combined functions (Supporting Information Notes S1). This formula was then applied to calculate the stem emissions between ground level (i.e. \( h = 0 \) m) and the maximum height (i.e. \( H = 5 \) m). In the few cases where weak negative stem fluxes were recorded, a linear function was used. The anti-derivative of the two combined functions was:
\[
F = 2\pi \int_0^H (a + bh + cd^h) db
= 2\pi e \left[ \left( \frac{b\ln(d)h - 1}{\log_e(d)} \right) + \frac{ad^h}{\ln(d)} \right]_0^H \quad \text{Eqn 4}
\]

Subsequently we measured tree fluxes for the three lower heights from all trees in a plot at each measurement occasion and integrated stem emissions over 5 m using the established relationships.

Upscaling from tree emissions to ecosystem stem emissions

After the integration of stem fluxes into tree emissions \( F_{\text{tree}} \) we averaged the stem emissions per species and plot. To relate stem emissions to the ecosystem surface we multiplied the fluxes by tree density.

Soil exchange measurements

We determined CH₄ gas exchange between the soil surface and the atmosphere \( R_{CH_4} \) adjacent (1 m from the trunk) to 1/3 of measured trees, which resulted in 115 soil flux measurements. The day before soil exchange measurement we inserted a lightweight polypropylene rim (inner diameter 30 cm, height 15 cm) 10 cm deep in the soil into the peat surface. For the measurements, we then slotted a cylindrical chamber (diameter 30 cm, height 20 cm) into the rim ensuring an airtight seal. To reduce disturbance of the soil surface, a 120 × 50 cm polystyrene board was used to kneel on during sampling. It is possible that accessing the sampling locations resulted in ebullition. Chamber CH₄ gas concentration was analysed using the UGGA and fluxes were calculated as described above. All flux series were inspected to ensure ebullition was not affecting the calculated fluxes.

Water level fluctuations

We monitored water level fluctuations at the plots using a 5 cm diameter perforated PVC dip well inserted into the ground. In addition to the in situ water level measurements we used water availability (a standard hydrological parameter based on the water balance) of the soils measured 10 km away at the research station of the Smithsonian Tropical Research Institute (STRI) in Bocas del Toro as an additional measure to describe the wetness of the soils. Details of this parameter are provided in Notes S2.

Physicochemical parameters

We collected 200 ml of porewater at a depth of 15 cm with a plastic syringe fitted with a tube that was push into the peat. We then transferred 100 ml to a plastic beaker and measured the dissolved oxygen (DO) with an optical probe, oxido-reduction potential, electrical conductivity and pH. The probes were connected to a labquest interface (Vernier, Beaverton, OR, USA).

Remaining porewater in the syringe was filtered through 0.2 μm Acrodiscs ( Pall, New York, NY, USA). After returning from the field, the tubes were stored at 4°C and shipped in a cooled box within 3 wk for analysis. We filtered 1 ml of the solution through pre-rinsed 0.45 μm cellulose acetate membrane filters (Whatman, Maidstone, UK) and used an ion chromatograph ( Dionex) to measure NO₃⁻, SO₄²⁻, Cl⁻, Ca²⁺, Mg²⁺, NH₄⁺ and K⁺. We measured dissolved organic carbon (DOC) and dissolved nitrogen (TN) using a TOC/TN analyser ( Shimadzu, Kyoto, Japan; TOC-VCPN).
Results

Forest structure and soil physicochemical properties

The most abundant species in the mixed forest stands were *P. copaifera* and *C. panamensis* followed by *E. precatoria*, *C. eliptica* and *R. taedigera*. *S. globulifera*, *Pithecollobium* sp. and *Ficus* sp. were also present but at lower density (Table 1). The *Camnosperma* forest was dominated by *C. panamensis* followed by *C. eliptica*, with other species at lower abundance (Table 1). Overall stand height was greatest at the *Camnosperma* forest site while stem density and basal area did not differ significantly among sites (Table 2).

Peat depth at the sites was c. 2.8–3.5 m, pH and conductivity were low, and Cl– and S2– concentrations indicate freshwater conditions (Table 2). There was no difference in macro nutrient content between the two forest types (Table 2). DO varied temporally from between 2–3 mg l–1 in the dry season of August 2013 to c. 7 mg l–1 in the wet season of December 2014. Both DO and conductivity were slightly higher at the mixed than the *Camnosperma* forest sites in December 2014. The high DO concentrations in December 2014 were accompanied by high redox potential (c. 350 mV). Photosynthetically active radiation below the canopy was low (<100 μmol m–2 s–1), reflecting the high canopy closure at both sites, and air and soil temperature were 28 and 26°C, respectively.

Variation in stem-level CH4 fluxes with height

Methane fluxes were higher closer to the ground, with the greatest fluxes at 35 cm above ground level (Fig. 2). On average, fluxes at 500 cm were 3.5% (0.35 mg m–2 d–1) of fluxes at 35 cm (9.97 mg m–2 d–1), while at 115 cm stem emissions were still

Mean and SE of the differences, F and P-values relating to differences between ‘stands’ in measured parameters each year are reported. NS, P > 0.1; bold, significant difference; italics, P = 0.05–0.1. CND, conductivity; DO, dissolved oxygen; TN, total dissolved nitrogen; T, temperature.
26% of those at 35 cm. At 500 cm the proportion of the flux at 35 cm was 0.18% for C. panamenis, 3.4% for C. eliptica, 5.7% for S. globulifera, 8.6% for P. copaifera and 54.7% for Pithecollobium sp.

Tree-level CH₄ emissions

Individual tree CH₄ emissions varied between fluxes near zero to 698 mg per tree d⁻¹ and CH₄ emissions varied strongly among species (F₁,291 = 28.7, P<0.001). Highest emissions were from C. panamenis and C. eliptica (Fig. 3) and the lowest emissions were from Pithecollobium sp. and P. copaifera. Regression analysis showed that 34% of the variance explained was attributed to species. The best model predicting tree CH₄ fluxes, which explained 54% of the variance, included depth at breast height (DBH), water level, soil temperature and soil CH₄ fluxes (Fig. 4; Table 3). Emissions were positively related to DBH, higher water levels and soil CH₄ emissions, and negatively related to soil temperature (wet soils were cooler, Fig. 4).

Daily averaged tree emissions were greatest in the wetter months of mid-October 2014 to January 2015, with means of 133 ± 22 mg per tree d⁻¹ during times of water levels above the surface, while fluxes were substantially lower with a mean of 20 ± 28 mg per tree d⁻¹ during days when the water table was below the peat surface (Fig. 4). Water availability measured at the nearest weather station correlated well with the water level measured in the peatland (F₁,300 = 316.25, P<0.001, r² = 0.51, water level (cm) = -45.89 + 0.3255 (water availability (mm)) as well as with soil temperature (r² = 0.58, P<0.0001).

Ecosystem-level tree CH₄ emissions

Soil CH₄ fluxes were generally large in comparison with stem fluxes, particularly from mixed forest sites (stand: F₁,37 = 4.63, P<0.05; air and soil temperature were significant covariates in the model: F₁,39 = 7.61; P<0.01 and F₁,39 = 9.92, P<0.01, respectively, Fig. 5a). By contrast, tree emissions on the stand level were greatest at Campnosperma sites (stand: F₁,45 = 25.64, P<0.001) with the highest emissions during flooded periods, in line with the fluxes from individual trees (Fig. 5b). The highest net ecosystem emissions (soil + trees) were at the mixed forest site, due to some very high soil CH₄ emissions, but there was no significant difference between stands (P=0.1; Fig. 5c). At the

Fig. 2 Fitted regression curves between the stem emissions and height of the measurement made for (a) Campnosperma panamenis, (b) Cassipourea eliptica, (c) Symphonia globulifera, (d) Prioria copaifera and (e) Pithecollobium sp. (n = 4). The regression models are reported in Supporting Information Notes S4.
Campnosperma sites tree emissions accounted for 30% of the net flux during flooded conditions (Fig. 5d).

Soil ecosystem fluxes at the mixed forest site were positively related to water level and air temperature and negatively related to soil temperature, while there was no significant relationship between soil CH4 fluxes and any of the environmental variables at the Campnosperma site (Fig. 6; Table 3). Ecosystem-level tree emissions were negatively related to soil temperature in both of the forest types (Fig. 7; Table 3).

Upscaling of tree CH4 emissions

Land cover classification of the wetland vegetation types showed that the two target vegetation stand types, mixed and C. panamensis-dominated forests, covered 62.1 and 8.8 km² of the wetland area, respectively (Fig. 8; Table S1). The other main vegetation types, palm, stunted forest and bog plain, covered 36.8, 25.9 and 17.5 km², respectively. The overall accuracy for the land cover classification was 84.4% (Table S1). When the ecosystem tree fluxes were scaled to the areas of the two forest types, net emissions from mixed and C. panamensis-dominated forests were 340.3 and 339.5 ± 92.7 kg CH4 d⁻¹, respectively, during the flooded period. Emissions dropped substantially to 80.1 ± 22.8 and 39.3 ± 9.8 kg CH4 d⁻¹ from mixed and C. panamensis forests, respectively, during the period of water tables below the surface.

Discussion

Our data demonstrate clear differences in both the magnitude and the proportion of tree stem and soil emissions in the two peatland forest communities examined with soil emissions dominating the ecosystem CH4 flux. Trees contributed 10–30% of the net ecosystem tree CH4 flux from C. panamensis stands, supporting our first hypothesis that tree CH4 emissions are an important contributor to net ecosystem CH4 fluxes. The high emissions from the C. panamensis stands agree with the high contribution of trees to net ecosystem CH4 emissions (62–87%) in peatlands in Central Kalimantan, Indonesia (Pangala et al., 2013), mineral floodplain soils in the Amazon (41–51%) (Pangala et al., 2017), and temperate forested wetlands dominated by Alnus glutinosa and Betula pubescens (27%) (Pangala et al., 2015).

The contrasting low emissions from the mixed forest site, where tree emissions represented only 0.5% of total ecosystem emissions, suggests strong differences in the contribution made from trees to net emissions between forest types.

Regarding the magnitude of emissions from tropical peatland trees, fluxes from the sites in Panama were much larger (i.e. 386 g ha⁻¹ d⁻¹) from C. panamensis stands (Fig. 5b) than ecosystem-level tree fluxes reported from the tropical peatlands in Kalimantan, which at 48 g ha⁻¹ d⁻¹ were in the same range as fluxes from our mixed forest stand and during periods of low water tables at the C. panamensis stand (Pangala et al., 2013). This suggests that CH4 emissions from trees in these neotropical peatlands are significantly lower but of the same order of magnitude as those from mineral soils of the Amazon floodplain, which range between 474 and 2866 g ha⁻¹ d⁻¹ (Pangala et al., 2017) and that tree emissions from neotropical peatlands outside Amazonia also have the potential to be strong CH4 sources.

The strong response of ecosystem-level tree emissions to the water table, soil temperature and stand type suggest that the
importance of tree emissions to net ecosystem emissions varies seasonally, and the magnitude of tree contribution to net ecosystem emissions varies across forest types. In previous studies, high soil CH4 emissions correlated with high tree emissions (Pangala et al., 2013, 2014, 2015). In line with these findings, soil CH4 fluxes in our study were positively related to emissions from individual trees (Table 3) and tree emissions were greater during the wet season (Fig. 4). However, this did not hold true on the ecosystem scale. It is likely that the strong negative relationship between soil temperature and ecosystem-level tree CH4 emissions (Fig. 7) is driven by waterlogging (wet soils are cooler, see Fig. 4) and by extension high CH4 production. The wider implications of these findings are that forest type and soil temperature could be used to predict tree CH4 emissions in tropical peatlands.

Methane emissions from stems varied by several orders of magnitude among species (Fig. 3). This supports results from other temperate and tropical peatland ecosystems, where species-specific differences were attributed to size, wood and lenticel density (Pangala et al., 2013, 2014). Furthermore, pneumatophore density (a species-level trait) determined peat surface CH4 emissions and, by extension, tree emissions in Southeast Asian peatlands (Pangala et al., 2013). In our study, stem emissions were greatest from the hardwood tree C. panamensis, this species forms dense monodominant stands, which explains the high stand-level CH4 emissions from this forest type and suggests that these sites may be hotspots of tree CH4 emissions. By contrast, the high emissions from C. eliptica and S. globulifera stems may be related to their growth habits: S. globulifera is a large canopy tree and CH4 emissions from individual trees were related to stem diameter, while C. eliptica is smaller and in Kalimantan smaller trees emitted more CH4 possibly due to greater lenticel densities or lower wood densities in smaller less mature trees (Pangala et al., 2013, 2014). Differences in lenticel densities may contribute to differences in tree emissions between the study species. Indeed, C. panamensis produced greater lenticel densities near the base of the trunk than C. eliptica, P. Copaifera and S. globulifera (O. Lopez, pers. obs.). S. globulifera also forms prop roots, an additional adaptation to wetland conditions that might further explain the high CH4 stem emissions for this species. At this stage it is not clear if stem CH4 emissions from the target species are transported via aerenchyma or through the xylem (Barba et al., 2018), and indeed it is possible that the emission pathway contributes to the differences noted among species. In this context it
is also important to note that lenticels/prop roots are physiological adaptations to support oxygen transport to the root system under flooded conditions (Kozlowski, 1984; McKee, 1993; Srikanth et al., 2016). Improved understanding and quantification of how different plant wetland adaptations impact both oxygen transport into the soil and gas transport back to the atmosphere for different species is critical to enable modelling and upscaling of these processes.

Parameter estimates and overall model statistics are reported. Bold P-values indicate significance. T, temperature; DBH, diameter at breast height; WT, water table; na, not applicable.

¹Water table (WT) above the peat surface is positive.

Fig. 5 Methane fluxes from (a) soil and (b) trees, (c) net ecosystem fluxes, and (d) relative contribution from trees at mixed and Campnosperma forests. Black bars are measurements made when the water table was above the peat surface (WL+) adjacent to the individual tree, while striped bars refer to water tables below the peat surface (WL−). Note the different scale between soil and tree fluxes. Means ± SE are shown.
The palm emitted little CH$_4$, perhaps because of the structure of its tissue (e.g. the distribution of the vascular bundles within the stems) or its capacity to oxygenate the root zone via extensive aerenchyma formation and reduce soil CH$_4$ production and hence the amount of CH$_4$ that could potentially be transported through its tissue (Hoyos-Santillan et al., 2016). If the low palm stem emissions are linked to its palm functional traits then this would suggest that stem emissions would not be a large contributor to net ecosystem CH$_4$ emissions from palm-dominated areas, such as the *Mauritia flexuosa*-dominated peat swamps in the Amazon (Draper et al., 2014). Wood density alone does not appear to explain the variation in CH$_4$ emission among species, because *C. panamensis* – the highest emitter – has low wood density (0.33 g cm$^{-3}$), yet the other high-emitters *C. eliptica* and *S. globulifera* have relatively high wood density (0.65 and 0.58 g cm$^{-3}$, respectively).

Plausible explanations for the very high CH$_4$ emissions from soil in our study site are high substrate availability in the form of poorly decomposed peat, and root exudates and anaerobic microsites within the upper peat layers resulting in high methanogenic activity, which is not abated by methane oxidation at the surface. High soil CH$_4$ emissions from
Camponsperma stands are driven in part by high DOC concentrations in the soil solution (Wright et al., 2013), suggesting substrate limitation of CH4 production (Hoyos-Santillan et al., 2016). The importance of substrate quality may also explain the high soil CH4 emissions from the mixed forest stand, which has been shown to have higher concentrations of long-chain n-alkane and high carbohydrate/aromatic ratios in surface peat than Camponsperma stands (Upton et al., 2018). However, incubation studies (Sjögersten et al., 2018) suggest comparable rates of CH4 production from surface peat in Camponsperma and mixed forest stands. This indicates that the differences observed in the field are linked to in situ variation in abiotic (e.g. water table, redox conditions, temperature, Fig. 6, 7; Table 3) and biotic drivers (e.g. root outputs of exudates and oxygen into the rhizosphere; Hoyos-Santillan et al., 2016; Girkin et al., 2018). The strong temporal differences in soil and tree emissions, with much stronger increases in stem emissions than soil emissions during the wetter period, suggests that trees are especially important transporters of CH4 during periods of high water tables. We speculate that this may be due to high CH4 production within the root zone during periods of waterlogging that subsequently result in high tree emissions. The lower substrate quality of old peat away from the immediate root zone, together with surface peat oxidation, may explain a less pronounced increase in CH4 emissions during periods of high rainfall.

Because trees of different species are able to strongly modify the physicochemistry (pH and redox) and substrate availability (Girkin et al., 2019) within their root zone, trees can directly impact soil CH4 production and oxidation. Therefore, a dominance of tree species and species physiological adaptation to flooding might modulate soil CH4 concentrations and stem emissions and therefore be critical to predict ecosystem-level CH4 emissions in tropical peatlands. If this is the case, understanding the physiological adaptations that impact soil biogeochemistry among different tree species is critical to predict ecosystem-level CH4 emissions.

Despite the much smaller areal extent of the C. panamensis stands, trees in this forest type contributed similar amounts of CH4 to the atmosphere as the mixed forest during flooded periods and contributed 50% of CH4 emissions during drier periods with water tables below the surface. This highlights that a spatially minor vegetation type can be a major contributor to overall tree CH4 emissions from an ecosystem. Upscaling of tree stem emissions must therefore consider the full range of vegetation types present in a given area to achieve realistic representation of this emissions pathway.

In conclusion, Neotropical peatlands are strong emitters of CH4, emissions from tree stems forming an important component. Stem emissions vary seasonally and among tree species, presenting a source of temporal variability in CH4 emissions from these ecosystems. We attribute contrasting tree CH4 emissions

---

**Fig. 8** Land cover distribution and areas of different vegetation types across the San San Pond Sak wetland system.
between the two forest types to: the dominance of the high emitter *C. panamenis*, the high tree density within the *Campnosperma*, and degree of waterlogging and magnitude of soil CH$_4$ emissions.
