Introduction Beagle 2 is a 72 kg probe (with a 32 kg lander) developed in the United Kingdom for inclusion on the European Space Agency’s 2003 Mars Express. Beagle 2 was launched on June 2, 2003 with Mars Express on a Soyuz-Fregat rocket from the Baikonur Cosmodrome in Kazakhstan. Beagle 2 landed on Mars on December 25th, 2003 in Isidis Planitia (~10.7°N and 268.6°W), a large sedimentary basin that overlies the boundary between ancient highlands and northern plains. Isidis Planitia, the third largest impact basin on Mars, which is possibly filled with sediment deposited at the bottom of long-standing lakes or seas, offers an ideal environment for preserving traces of life. The team is awaiting signals from the Beagle 2 lander at the time when this abstract was written. Current status of the mission will be reported.

Beagle 2 was developed to search for organic material and other volatiles on and below the surface of Mars in addition to the study of the inorganic chemistry and mineralogy [1-3]. Several fundamental properties can be used to determine the existence of an active or past biology on any planet, Earth or Mars. Beagle 2’s targets for investigation included:

(a) the presence of water, or the existence of minerals deposited from water to show that water was present, even if only transiently
(b) the detection of carbonaceous debris, the remains of organisms that might have lived in water or were washed to a final resting place by the action of water
(c) the structure of organic matter, to demonstrate that it might have been synthesized for a biological purpose
(d) the recognition of isotopic fractionation between carbonaceous phases (organic vs inorganic carbon phases), a condition which on Earth suggests that life emerged nearly 4 billion years ago.

Instrument Package Beagle 2 utilizes a mechanical mole and grinder to obtain samples from below the surface, under rocks and inside rocks. A pair of stereo cameras will image the landing site along with a microscope for examination of surface and rock samples. Analyses will include both rock and soil samples at various wavelengths, X-ray spectrometry and Mossbauer spectrometry as well as a search for organics and other light element species (e.g. carbonates and water) and measurement of their isotopic compositions. Beagle 2 has as its focus the goal of establishing possible evidence for whether life existed in the past on Mars or at least establishing if the conditions were ever suitable.

A mechanical arm (PAW) is used for science operations along with sample acquisition. Instruments attached to the PAW include: stereo cameras, Mossbauer and X-ray fluorescence instruments, microscope, environmental sensors, rock corer/grinder, a spoon, mirror, brushes, a Mole attachment for acquisition of subsurface samples to depths of 1 to 2 meters and an illumination device. Each camera has 14 filters, which have been optimized for identifying the chemical composition of samples, including dust particles, and the detection of water vapor. The microscope’s camera is designed for viewing the size (down to 4 microns) and shape of dust particles, rock surfaces, microfossils, and characteristics of the samples prior to introduction into the gas analysis package (GAP). The microscope features 4-color capability (red, green, blue and UV fluorescence), a depth of focus of 40 micrometers and translation stage of ±3 millimeters.

Beagle 2’s heart is the life detection package which is a gas analysis package (GAP) consisting of a mass spectrometer with collectors at fixed masses for precise isotopic ratio measurements and voltage scanning for spectral analysis. The primary aim of the GAP is to search for the presence of bulk constituents, individual species, and isotopic fractionations for both extinct and extant life along with studying the low-temperature geochemistry of the hydrogen, carbon, nitrogen and oxygen components from both the surface and atmosphere. GAP uses a 6 cm radius magnetic sector mass spectrometer (mass range of 2 to 140 amu) which can be operated in both the static and dynamic modes. A triple Faraday collector array will be used for C, N and O ratios along with a double
Faraday array for H/D. A pulse counting electron multiplier will be utilized for noble gases and selected organics. Anticipated detection limits are at the picomole level for operation in the static mode of operation and high precision isotopic measurements will be made in the dynamic mode. Sample processing and preparation system consists of reaction vessels along with references. The sample ovens capable of being heated are attached to the manifold for sample combustion. Surface, subsurface materials and interior rock specimens will be combusted in pure oxygen gas at various temperature intervals to release organic matter and volatiles. Combustion process will permit detection of all forms and all atoms of carbon present in the samples. A chemical processing system is capable of a variety of conversion reactions. Gases are manipulated either by cryogenic or chemical reactions and passed through the gas handling portion of the vacuum system. There are two modes of operation: quantitative analysis and precise isotopic measurements.

Three main types of analysis will be carried out by the GAP:

(1) search for organic matter
(2) stepped combustion for total light element content and speciation
(3) atmospheric analysis.

Isotopic measurement of H/D, $^{13}$C/$^{12}$C, $^{15}$N/$^{14}$N and $^{18}$O/$^{16}$O and the search for possible biogenic methane within the Martian atmosphere will be made. Estimates of the present methane concentration in the atmosphere is believed to be <100 ppb. Lifetime of CH$_4$ in Mars’ atmosphere is believed to be < 300 years and therefore no abiogenic methane is anticipated. The GAP is capable of concentrating gases and the search for biogenic atmospheric methane will be made. The mass spectrometer will operate in the static mode for the CH$_4$ measurements after chemical reagents have concentrated the atmospheric gases. Conversion to a measureable component will be made to ensure no false positive results will be obtained along with lowering the detection limits. Should methane be detected within the Martian atmosphere its putative source would have to be biogenic (i.e. methanogenic bacteria).

An environmental sensor system for surface temperatures, atmospheric pressures, wind speed and direction accompanies atmospheric sampling. The local radiation environment’s dose and rates will be characterized. UV flux at the lander is measured in a variety of wavelengths longer than 200 nm, information relevant to understanding the survival of organics. High sensitivity isotopic analysis of the carbon species present within the samples makes no assumptions about the biochemistry on Mars but provides clues to past life as inferred from the isotopic fractionations measured directly on Mars. Planetary protection protocols were followed for Beagle 2. The lander has been designated as a Category IVA+ mission. A microbial reduction plan was in place and all components were sterilized. Additional cleaning procedures including vacuum baking were followed to reduce blanks associated with GAP operations.
