Herschel-ATLAS: Dust temperature and redshift distribution of SPIRE and PACS detected sources using submillimetre colours

(Affiliations are available in the online edition)

Received 30 March 2010 / Accepted 26 April 2010

We present colour–colour diagrams of detected sources in the Herschel-ATLAS science demonstration field from 100 to 500 μm using both PACS and SPIRE. We fit isothermal modified black bodies to the spectral energy distribution (SED) to extract the dust temperature of sources with counterparts in Galaxy And Mass Assembly (GAMA) or SDSS surveys with either a spectroscopic or a photometric redshift. For a subsample of 330 sources detected in at least three FIR bands with a significance greater than 3σ, we find an average dust temperature of (28 ± 8) K. For sources with no known redshift, we populate the colour–colour diagram with a large number of SEDs generated with a broad range of dust temperatures and emissivity parameters, and compare to colours of observed sources to establish the redshift distribution of this sample. For another subsample of 1686 sources with fluxes above 35 mJy at 350 μm and detected at 250 and 500 μm with a significance greater than 3σ, we find an average redshift of 2.2 ± 0.6.

Key words. submillimeter: galaxies – Galaxy: evolution – galaxies: high-redshift

1. Introduction

The total intensity of the extragalactic background light at far-infrared (FIR) wavelengths has been measured with absolute photometry (Puget et al. 1996; Fixsen et al. 1998; Dwek et al. 1998). Deep surveys are now starting to resolve the cosmic FIR background into discrete sources with the fraction resolved varying with wavelength (see reviews in Blain et al. 2002; Hauser & Dwek 2001; Lagache et al. 2005; Dye et al. 2009). Despite some successes, there are still large uncertainties about the nature and evolution of the submillimetre (submm) galaxy population, including their redshift distribution.

The Herschel Astrophysical Terahertz Large Area survey (H-ATLAS) is an open-time key program of the Herschel Observatory (Pilbratt et al. 2010) that will survey roughly 550 deg2 of sky over 600 h of observations (Eales et al. 2010). To cover the widest possible area, H-ATLAS uses the maximum possible scan rate for the telescope at 60 arcsec s−1 in the parallel mode of PACS (Poglitsch et al. 2010) and SPIRE (Griffin et al. 2010). The observations cover five photometric bands with 100 and 160 μm data from PACS, and 250, 350, and 500 μm data from SPIRE. The H-ATLAS fields include 1 field close to the northern Galactic pole (150 deg2), 3 fields (each 36 deg2) coinciding with the GAMA redshift survey fields (Driver et al. 2009), and 2 fields (total area of 250 deg2) near the southern Galactic pole.

During the science demonstration phase (SDP), H-ATLAS observed 14.4 deg2 in the GAMA-9 h field near the ecliptic plane to a 5σ depth of 35–90 mJy. In this Letter we present the colour–colour diagrams derived from the five bands from 100 to 500 μm for the H-ATLAS sources that are cross-identified in at least 3 of the SPIRE and PACS bands. We then discuss the dust temperature and redshift distributions based on certain assumptions about the spectral energy distribution (SED) and subject to selection effects associated with the sample selection.

2. Colour–colour diagrams

We use source catalogues generated for the H-ATLAS consortium by Rigby et al. (in prep.), derived from SPIRE and PACS maps presented in Pascale et al. (in prep.) and Ibar et al. (in prep.), respectively. The source catalogues are supplemented with cross-identification information from the GAMA survey (Driver et al. 2009) and SDSS DR-7 (Abazajian et al. 2009) as...
described in Smith et al. (in prep.). For the sources for which spectroscopic redshifts from GAMA or SDSS are not available, we use photometric redshifts generated using the ANNz neural network code (Collister & Lahav 2004), trained with photometry from SDSS and UKIDSS LAS (Lawrence et al. 2007), and spectra from the GAMA spectroscopic survey (Driver et al. 2009), DEEP2 (Davis et al. 2007), zCOSMOS (Lilly et al. 2007), and the 2SLAQ-LRG (Cannon et al. 2006) survey.

In Fig. 1, we show the colour–colour plots of the H-ATLAS sources. We divide these plots in terms of colours based on either SPIRE only or SPIRE and PACS data. Our flux selection results in selecting 1686, 402, and 158 sources, from top to bottom of Fig. 1. For reference, the total ATLAS catalogue for this field contains ~6600 sources (Rigby et al., in prep.).

The colour–colour plots are filled with 10^6 black-body spectra at a single dust temperature, T_d, modified by a frequency-dependent emissivity function \( \epsilon_\nu \propto \nu^{\beta} \), where the flux density \( f_\nu \) is

\[
 f_\nu = \epsilon_\nu B_\nu \propto \nu^{\beta} \left[ \exp \left( \frac{h\nu}{kT_d} \right) - 1 \right].
\]  

(1)

In generating these models, we consider uniform ranges of dust temperature from 10 to 60 K, emissivity parameter \( \beta \) from 0 to 2, and redshift from 0 to 5. The choice of \( 0 < \beta < 2 \) compared to \( 1 < \beta < 2 \) makes a minor difference since we also broaden the SED tracks in the colour diagram by adding an extra Gaussian standard deviation of 10% to the fluxes used to compute the model colour. This scatter accounts for the broadening of data in the colour–colour plane caused by flux uncertainties. As shown in Fig. 1, we find that the colour diagram of sources with fluxes only from SPIRE are well within the limits defined by the models we have considered. When we examine PACS colours, we find that some points lie outside the same set of tracks as used for the SPIRE-only colour diagram. While some of these outlier points may be caused by either the fractionally larger flux errors of PACS or contamination from a neighboring source, it is possible that some of these sources are not accurately described by our simple isothermal SED model, requiring for instance a second dust component (Dunne & Eales 2001) or a more complex SED model.

When fitting a simple modified black-body model to the data, we must keep in mind that there is a partial degeneracy between \( \beta \) and \( T_d \) and, more importantly, a perfect degeneracy between \( T_d \) and \( z \). The peak of the SED is determined by the \( \nu/T_d \) term in the exponential, so that a measurement of the colours alone constrains only the ratio \( (1 + z)/T_d \). However, assuming reasonable priors on the free parameters of the SED model (in our case, \( \beta \) and \( T_d \)) it is still possible to estimate a qualitative redshift distribution for our sample of sources. Alternatively, if secure redshifts are known from optical cross-identifications, we can determine the dust temperatures.

### 3. Dust temperature distribution

We consider the H-ATLAS source sample with detections at \( 3\sigma \) in at least two bands and at \( 5\sigma \) in one band of either PACS and SPIRE that have been robustly identified with GAMA or SDSS DR-7 galaxies. We also require that there is a known spectroscopic redshift from either GAMA or SDSS, or from the photometric redshift catalog (with \( (1 + z)/\sigma_z > 5 \) and \( z/\sigma_z > 1 \)) that was generated for this field and cross-identified with ATLAS sources (Smith et al., in prep.). We select 330 sources, which correspond to the low redshift subsample of the galaxies selected in the colour–colour diagrams. For each galaxy, we perform a single temperature fit from the above equation assuming \( \beta = 1.5 \). We found that an isothermal SED model generally is a good fit to the 330 galaxies. Fitting a two-component SED model does not, on average, seem to provide a closer fit. The relatively good fit provided by the isothermal SED model is probably due to most of our sample consisting of low redshift galaxies and therefore that we do not probe much of the Wien part of the galaxy SED.
In Figs. 2 and 3 (including H-ATLAS).

they are: (i) the sources in BLAST detected above 5
μm and complemented with IRAS 60 and 100
The large expected sample of sources from the 550 deg$^2$ of H-ATLAS will
enable more detailed studies in the future, without the biases asso-
ciated with selections of various sub-samples, including our
own. While we show results here with β = 1.5 fixed, when fit-
ing for β and $T_\alpha$ we found β = 1.4 ± 0.1, consistent with β = 1.3
found in Dunne et al. (2000).

In Fig. 3, we plot the dust temperature versus FIR lumin-
osity by integrating model SEDs between 8 and 1100 μm for the
H-ATLAS subsample. Luminosities for other samples are
from the literature. Fitting for a relation of the form $T_\alpha = T_\alpha + \alpha \log(L_{\text{FIR}}/L_\odot)$, we find $T_\alpha = -20.5$ K and $\alpha = 4.4$ (see, Fig. 4). The value of $\log(L_{\text{FIR}}/L_\odot)$ is on average 10.9 ± 0.8 for our
sample. This relation is consistent with the BLAST data (Dye et al. 2009).

4. Redshift distribution

Since most of our sources lack redshifts, we consider another
example application of our colour diagram and infer the statistical
redshift distribution $N(z)$ for the source samples plotted in
Fig. 1. We do this by first gridding the colour–colour plane along the
SED tracks into redshift bins. We then convert the number
of sources within a grid region of colours to a binned redshift
distribution (Hughes et al. 2002). This method is equivalent to
extracting the redshift probability distribution function for the
whole sample if we had simply fitted SEDs to individual fluxes
and taken the sum of the redshift probabilities of each source.
While the redshift for an individual galaxy is largely uncertain,
Figure 4. Normalized redshift distribution (black thick solid line) of SPIRE sources in the colour–colour diagram of Fig. 1a, selected to satisfy the following criteria: $S_{350} > 35$ mJy and at least $3\sigma$ detections at 250 and 500 $\mu$m. The dashed line and dotted-dash line represent Negrello et al. (2007) and Lagache et al. (2004) models for the same flux selection. Both model curves have similar but not identical distributions, although Lagache model predicts a larger number of high-redshift galaxies. In addition, we show $N(z)$ for the same subsample using a colour-cut of $S_{350}/S_{250} > 0.75$ (blue thin solid line), and $>0.75$ (red thin dotted line). The distribution shown here is for 1686 sources, a subset of about 6600 H-ATLAS sources in the SDP field.

and sensitive to the SEDs used, the statistical redshift distribution we extract should be a reasonable estimate of the true distribution of the source sample.

Figure 4 shows the redshift distribution for SPIRE sources detected in all 3 bands (Fig. 1a). For the sample of 1686 sources with flux densities above 35 mJy at 350 $\mu$m and above 3$\sigma$ at 250 and 500 $\mu$m, we find the average redshift to be $2.2 \pm 0.6$. This is consistent with the average redshift of 2.4 $\pm$ 0.4 for the radio-identified sub-mm galaxies with SCUBA at 850 $\mu$m followed up spectroscopically at Keck (Chapman et al. 2005), the interquartile redshift range of 1.8 to 3.1 for sources in SCUBA Half Degree Extragalactic Survey determined photometrically (Aretxaga et al. 2007), and a median redshift of greater than 1 for a subsample of 250 $\mu$m sources as faint as 35 mJy (Dunlop et al. 2009). Our distribution, however, has an average redshift that is higher than that of a larger sample of BLAST sources (Dye et al. 2009). This difference is not unexpected given the differences in the sample selection. We emphasize again that the distribution shown in Fig. 4 is for a subset of about 25% of the whole catalog with specific selection criteria that tend to favour the high-redshift-end of the distribution. Based on cross-identifications with SDSS and GAMA, we find that 30% of the H-ATLAS sources are at $z < 0.5$ in the SDP field (Smith et al., in prep.).

In addition to the total sample, we also make a colour-cut with $S_{350}/S_{250} > 0.75$ and $<0.75$, in addition to the flux cut of 35 mJy at 350 $\mu$m. By imposing this colour-cut, we distinguish a high redshift population with redder colours from a low redshift population. We find average redshifts of 2 $\pm$ 0.7 for sources detected in 160, 250, and 350 $\mu$m with a flux cut of 35 mJy at 250 $\mu$m, and $z = 0.7 \pm 0.3$ for sources detected in 100, 160, and 250 $\mu$m with a flux cut of $\geq 100$ mJy at 160 $\mu$m. As is clear from Fig. 1, we find that lower redshift sources are more likely to be detected at shorter wavelengths, while bright sources seen in longer SPIRE bands are likely to be on average at high redshifts. Some of the bright 500 $\mu$m sources that we detect, especially with a colour selection selecting red galaxies in the sub-mm, may also have their fluxes magnified by lensing and will be among the results forthcoming from H-ATLAS (Negrello et al., in prep.).

5. Conclusions

We have discussed the spectral energy distribution of sub-mm galaxies in a 14 deg$^2$ subsample of the full H-ATLAS survey. We have used the colours in 5 bands to measure the dust temperature for the sub-sample of sources with known redshifts. We have also derived a qualitative estimate of the statistical redshift distribution of bright 350 $\mu$m selected galaxies assuming broad priors in temperature and the dust emissivity. We found that the average dust temperature of H-ATLAS sources is $28 \pm 8$ K, while 350 $\mu$m sources with fluxes above 35 mJy have an average redshift of $2.2 \pm 0.6$.
