LETTERS

No extreme bipolar glaciation during the main Eocene calcite compensation shift

Kirsty M. Edgar¹, Paul A. Wilson¹, Philip F. Sexton^{1†} & Yusuke Suganuma²

Major ice sheets were permanently established on Antarctica approximately 34 million years ago^{1–3}, close to the Eocene/Oligocene boundary, at the same time as a permanent deepening of the calcite compensation depth in the world's oceans⁴. Until recently, it was thought that Northern Hemisphere glaciation began much later, between 11 and 5 million years ago^{1–3,5}. This view has been challenged, however, by records of ice rafting at high northern latitudes during the Eocene epoch^{6,7} and by estimates of global ice volume that exceed the storage capacity of Antarctica⁸ at the same time as a temporary deepening of the calcite compensation depth ~41.6 million years ago⁹. Here we test the hypothesis that large ice sheets were present in both hemispheres ~41.6 million years ago using marine sediment records of oxygen and carbon isotope values and of calcium carbonate content from the equatorial Atlantic Ocean. These records allow, at most, an ice budget that can easily be accommodated on Antarctica, indicating that large ice sheets were not present in the Northern Hemisphere. The records also reveal a brief interval shortly before the temporary deepening of the calcite compensation depth during which the calcite compensation depth shoaled, ocean temperatures increased and carbon isotope values decreased in the equatorial Atlantic. The nature of these changes around 41.6 million years ago implies common links, in terms of carbon cycling, with events at the Eocene/Oligocene boundary⁴ and with the 'hyperthermals' of the Early Eocene climate optimum^{3,10,11}. Our findings help to resolve the apparent discrepancy between the geological records of Northern Hemisphere glaciation^{6–8} and model results^{12,13} that indicate that the threshold for continental glaciation was crossed earlier in the Southern Hemisphere than in the Northern Hemisphere.

A striking feature of the composite³ Cenozoic $\delta^{18}\text{O}$ record in benthic foraminiferal calcite is the abrupt increase in values across the Eocene/Oligocene boundary, 34 Myr ago (Fig. 1a). Together with evidence from Southern Ocean records for the initiation of ice rafting¹⁴ and glacial weathering, and from sequence stratigraphic studies¹⁵ for a global sea level fall (~70 m apparent sea level), this $\delta^{18}\text{O}$ shift is widely interpreted to signify the onset of major Antarctic glaciation^{1–3,14} (Fig. 1a). The standard view^{1–3,5} is that substantial Northern Hemisphere glaciation occurred much later (Fig. 1a); recently, however, three lines of evidence have challenged this orthodoxy.

First, evidence now exists for ice rafting in the Arctic Ocean around 45 Myr ago⁶ and in the Norwegian–Greenland Sea between 37 and 27 Myr ago⁷ (Fig. 1a). Second, new records for the Eocene/Oligocene boundary from the equatorial Pacific Ocean (ODP Leg 199 of the Ocean Drilling Program) show⁴ that the amplitude of the $\delta^{18}\text{O}$ change ($\Delta\delta^{18}\text{O}_{\text{benthic}} = 1.5\text{‰}$ VPDB) is impossibly large to be attributed to Antarctic glaciation alone. The simplest explanation for this result is that some of the $\Delta\delta^{18}\text{O}_{\text{benthic}}$ signal must denote global cooling⁴. However, Mg/Ca records^{2,16} provide little support for declining

temperatures. This raises the possibility of ice growth beyond Antarctica and/or the operation of some factor (such as changes in seawater carbonate chemistry associated with increasing calcite compensation depth, CCD) acting to mask the cooling signal in the Mg/Ca records^{4,16}. Third, the $\delta^{18}\text{O}$ increase associated with the Eocene/Oligocene boundary occurred in lock-step with permanent deepening of the CCD, possibly in response to glacioeustatic sea level fall and reduced shelf carbonate accumulation⁴. Thus, the discovery^{9,17} of multiple intervals of temporary CCD deepening in the equatorial Pacific earlier in the Eocene (Fig. 1b) has prompted speculation of transient glaciations before the Eocene/Oligocene boundary. A recent study⁸ invokes three such glaciations including one extreme bipolar event (100–190 m apparent sea level change; $\sim 35\text{--}70 \times 10^6 \text{ km}^3$ ice) coincident with the most prominent of the transient Eocene CCD deepening events (carbonate accumulation event CAE-3 ~41.6 Myr ago; ref. 9 and Fig. 1b, c). Yet the idea that large ice sheets existed in both hemispheres at this time is at odds with contemporaneous warm polar ocean temperatures^{2,3,18}, high atmospheric CO_2 levels¹⁹ (Fig. 1a) and the occurrence of (sub)tropical flora at mid- to high latitudes²⁰. Sequence stratigraphic records²¹ support the concept of early Cenozoic glaciations, but the ice sheets invoked are much more modest in size (~10 to 45 m apparent sea level change; ~40 to 65% of present East Antarctic ice sheet) and considered compatible with high-latitude warmth because of their restriction to the interior of Antarctica²¹.

Although the sensitivity to CCD change¹⁷ of the Pacific drill sites used to infer extreme bipolar Eocene glaciation is beneficial to understanding carbon cycling, it is detrimental to generating isotope records from calcareous microfossils whose occurrence and preservation are sensitive to changes in carbonate saturation state. Thus, further tests of bipolar Eocene glaciation are warranted. We generated high-resolution (~4.5 kyr) monospecific stable isotope records for the interval spanning CAE-3 (ref. 9) from the equatorial Atlantic Ocean (ODP Leg 207, Demerara Rise, Site 1260, 9° 16' N, 54° 33' W; palaeowater depth 2,500–3,000 m)²². These sediments were deposited well above the local CCD for most of the study interval and are shallowly buried²², favouring calcareous microfossil preservation¹⁸.

In Fig. 1c–e, we compare our new $\delta^{18}\text{O}$ records from the equatorial Atlantic with the record presented⁸ from the equatorial Pacific in support of bipolar glaciation. $\delta^{18}\text{O}$ data from the equatorial Pacific show a considerable spread, and the amplitude of increase used to infer extreme bipolar glaciation relies on outliers in sparse data ($\Delta\delta^{18}\text{O}_{\text{benthic}} = 1.2\text{‰}$ VPDB, arrows, Fig. 1c). Our data from the Atlantic are more continuous and show less spread (Fig. 1d, e). Our benthic record (Fig. 1d) shows a well-defined minimum around the middle of magnetochron C19r followed by a shift to higher values attained by the onset of CAE-3 (zone I/II boundary, Fig. 1c). Our planktic record shows a similar pattern (Fig. 1e). One interpretation of the correspondence between our planktic and benthic records is

¹National Oceanography Centre, School of Ocean and Earth Science, European Way, Southampton, SO14 3ZH, UK. ²Department of Earth & Planetary Science, University of Tokyo, 7-3-1 Hongo Bunkyo-ku, Tokyo, 113-0033 Japan. †Present address: Scripps Institution of Oceanography, University of California, San Diego, La Jolla, California 92093-0244, USA.

that it reflects an increase in the oxygen isotope composition of sea water ($\delta^{18}\text{O}_{\text{seawater}}$) and supports the notion of ice growth. Another interpretation, arguably more in keeping with the other palaeoclimate records¹⁹ and numerical modelling results^{12,13} shown in Fig. 1a, is that our data are attributable to cooling of surface and bottom waters at Site 1260. Regardless, our estimate of the $\Delta\delta^{18}\text{O}_{\text{benthic}}$ signal associated with CAE-3 is about half that proposed⁸ from the Pacific (Fig. 1d versus Fig. 1c).

In Fig. 2 we show the relationship between measured $\Delta\delta^{18}\text{O}_{\text{benthic}}$ and global continental ice volumes for a range of values for mean $\delta^{18}\text{O}$ of stored ice ($\delta^{18}\text{O}_{\text{ice}}$). Horizontal dashed lines denote different values for $\Delta\delta^{18}\text{O}_{\text{benthic}}$, vertical solid lines correspond to different values assumed for $\delta^{18}\text{O}_{\text{ice}}$ and intersections yield the resulting estimated ice volumes (see 'isovol' lines). Lines a and b assume that the whole $\Delta\delta^{18}\text{O}_{\text{benthic}}$ signal is attributable to ice volume. Assuming that $\delta^{18}\text{O}_{\text{ice}}$ was as extreme as today (about -50% SMOW^{4,23}), the $\Delta\delta^{18}\text{O}_{\text{benthic}}$ signal inferred in the Pacific study⁸ for CAE-3 (line a in Fig. 2) yields a global middle Eocene ice budget almost 1.5 times the present Antarctic ice volume ($25.4 \times 10^6 \text{ km}^3$)²⁴. However, the latitudinal temperature gradient during the Eocene was less extreme than today, so it is likely that $\delta^{18}\text{O}_{\text{ice}}$ was also less extreme (conservatively, about -30% SMOW^{4,23,25}), yielding even larger ice budgets (almost 2.5 times the modern Antarctic budget). This ice volume is close to the global total estimated for the last glacial maximum (Fig. 2), when large ice sheets existed not only on Antarctica and Greenland but also over large areas of North America and Eurasia, and it implies an even greater global ice budget for the Eocene/Oligocene boundary when benthic $\delta^{18}\text{O}$ values were $\sim 0.8\%$ higher

(Fig. 1a). Even larger ice volumes were invoked⁸ for CAE-3 in the Pacific study using the dual benthic Mg/Ca – $\delta^{18}\text{O}$ method ($\Delta\delta^{18}\text{O}_{\text{seawater}} = 1.5\%$). But we focus on the $\Delta\delta^{18}\text{O}_{\text{benthic}}$ signal alone because the presence of authigenic dolomite^{16,17} towards the base of the section at ODP Site 1218 means that the only potentially meaningful Mg/Ca data published for CAE-3 are for its termination (see figure 3 of ref. 8). By focusing on the $\Delta\delta^{18}\text{O}_{\text{benthic}}$ signal alone we adopt a conservative approach because the ice budgets calculated in this way in ref. 8, although extreme (because the whole signal was attributed to ice growth with no associated cooling), are less extreme than those that were estimated by the dual benthic Mg/Ca – $\delta^{18}\text{O}$ method.

If we assume no cooling component associated with the smaller $\Delta\delta^{18}\text{O}_{\text{benthic}}$ signal seen in our new record (line b, Fig. 2), our revised estimate of the upper limit of possible ice growth associated with CAE-3 is correspondingly smaller, it need not require ice storage in the Northern Hemisphere and it is more in keeping with sequence stratigraphy records²¹. On this basis, we cannot exclude the possible existence of small valley glaciers draining the uplands of Greenland around 41.6 Myr ago, particularly in light of dropstones recently discovered^{6,7} in Eocene strata in the high northern latitudes. Nevertheless, we can rule out the existence of large ice sheets in the Northern Hemisphere and we therefore find no support for extreme Eocene bipolar glaciation. Based on work elsewhere^{23,26} we might expect the $\Delta\delta^{18}\text{O}_{\text{benthic}}$ signal to be composed of at least equal parts ice volume and temperature (line b', Fig. 2). On this basis we calculate ice budgets that are easily accommodated on central Antarctica alone (~ 0.4 to 0.6 times modern Antarctic budget). Under these circumstances, only by assuming an extremely high value for

Figure 1 | Palaeoceanographic records showing changes in ocean chemistry and global climate. **a**, Cenozoic atmospheric CO_2 (ref. 19), grey shading defines the range of estimated CO_2 values as calculated in ref. 19 relative to the pre-anthropogenic level (PAL). Vertical dashed blue lines are model-defined thresholds for large ice sheet initiation. SHG and NHG, Southern and Northern Hemisphere glaciation^{12,13}. Composite benthic $\delta^{18}\text{O}$ record³. Vertical blue bars show the standard view of the presence and extent of full scale/permanent ice sheets (solid bars) and those thought to have been partial/ephemeral (broken bars). Occurrence of newly documented ice rafted debris (IRD) from the high northern latitudes is also shown^{6,7}. EEO, Early Eocene Climatic Optimum. **b**, CaCO_3 mass accumulation rate for the equatorial Pacific^{9,29}. The inset shows the classic CCD record for the equatorial Pacific 50 Myr ago to the present, with the pink-shaded zone

indicating the interval of transient CCD events⁹. Epochs are indicated (abbreviated) to the left of **a** and in the inset. **c**, Benthic $\delta^{18}\text{O}$ record from ODP Site 1218 (the dark green data points are from ref. 8 and yellow ones are from ref. 16). The shaded grey zones are: I, pre-onset of CAE-3; II, onset-to-peak CaCO_3 mass accumulation rate during CAE-3; III, post-peak CaCO_3 mass accumulation rate during CAE-3. Red arrows denote data points defining⁸ a 1.2% amplitude of $\delta^{18}\text{O}$ increase ($\Delta\delta^{18}\text{O}$) and thus the hypothesized extreme bipolar glaciation. **d**, **e**, New benthic and planktic $\delta^{18}\text{O}$ records from ODP Site 1260. Median values (white lines) and 1σ variance (shaded envelopes) are shown in **c**, **d** and **e**. Vertical dashed red lines in **d** denote our smaller estimate of $\Delta\delta^{18}\text{O}$ ($\sim 0.6\%$ VPDB), derived from the maximum and minimum values in the 1σ envelope of the benthic record. Magnetochrons are indicated to the left of **c**.

$\delta^{18}\text{O}_{\text{ice}}$ akin to the average for high altitude glaciers in the temperate zone today ($\geq -15\text{‰}$ SMOW) does the calculated ice volume exceed the modern budget for Antarctica (Fig. 2).

The main reason why the ice budgets of ref. 8 are so large is because their estimate of $\Delta\delta^{18}\text{O}_{\text{benthic}}$ was based on outlying data points and their isotope record is particularly sparse towards the top of magnetochron C19r (note the coring gap on the run up to CAE-3 and inferred glaciation, at the zone I/II boundary in Fig. 1c). To assess this interval in more detail we show an expanded version of our

Figure 3 | Palaeoceanographic records from ODP Site 1260 showing the run-up to CAE-3. We note the short-lived interval of CCD shoaling and ocean warming around 75 metres composite depth. **a**, Benthic $\delta^{13}\text{C}$ data. **b**, Planktic $\delta^{13}\text{C}$ data. **c**, Benthic $\delta^{18}\text{O}$ data. **d**, Planktic $\delta^{18}\text{O}$ data. **e**, Bulk

Figure 2 | Measured increases in $\delta^{18}\text{O}$ in benthic foraminifera ($\Delta\delta^{18}\text{O}_{\text{benthic}}$) and resulting global continental ice volumes for a range of values for the mean $\delta^{18}\text{O}$ of stored ice ($\delta^{18}\text{O}_{\text{ice}}$). Horizontal dashed lines indicate different values for $\Delta\delta^{18}\text{O}_{\text{benthic}}$ (described in the text) and assume $\Delta\delta^{18}\text{O}_{\text{benthic}} = 100\%$ ice volume (a, equatorial Pacific⁸; b, equatorial Atlantic, this study). Thick vertical lines correspond to different values of $\delta^{18}\text{O}_{\text{ice}}$ (estimated $\delta^{18}\text{O}_{\text{ice}}$ today at -50‰ and for the Middle Eocene at -30‰). Intersections yield resulting calculated ice volume shown by 'isovols' (values shown are $\times 10^6 \text{ km}^3$). The horizontal dashed line labelled b' corresponds to $\Delta\delta^{18}\text{O}_{\text{benthic}} = 0.6\text{‰}$, with 50% of that signal attributable to ice. Present Antarctic ice volume (PAIV)²⁴, Antarctic ice volume at the Last Glacial Maximum (ALGM)³⁰ and total global ice volume at the Last Glacial Maximum (GLGM) shown for reference. SMOW, standard mean ocean water.

foraminiferal $\delta^{18}\text{O}$ series together with accompanying $\delta^{13}\text{C}$, lithological and bulk sediment records in Fig. 3. Excursions to lower values of $\delta^{18}\text{O}$ (by $\sim 0.4\text{‰}$) and $\delta^{13}\text{C}$ (by 1.2–1.5‰) occur in both benthic and planktic records. These are accompanied by prominent decreases in bulk $\delta^{18}\text{O}$ (by 1.8‰) and $\delta^{13}\text{C}$ (by 1.1‰) within magnetochron C19r, across a 30 cm interval containing a highly dissolved foraminiferal assemblage and a well-developed red clay horizon where carbonate content falls sharply from ~ 75 weight percent CaCO_3 to a minimum of ~ 35 weight percent CaCO_3 (Fig. 3f). This event goes undetected in the equatorial Pacific record, presumably because it falls in the core gap at ODP Site 1218 (Fig. 1c) and therefore cannot explain the discrepancy between the two $\Delta\delta^{18}\text{O}_{\text{benthic}}$ signals shown in Fig. 1. On the other hand, our records show that, while ODP Site 1260 remained above the CCD for the vast majority of the study interval, shortly before the CCD deepened in the equatorial Pacific (CAE-3 in Fig. 1), it shoaled in the equatorial Atlantic sufficiently to be readily detectable at a water depth of about 3.0 to 2.5 km. In this respect, our records resemble those for the Eocene/Oligocene boundary where the CCD shoals sufficiently to completely eliminate CaCO_3 burial at ODP

sediment lightness²². **f**, Bulk sediment weight % CaCO_3 . **g**, Bulk sediment $\delta^{13}\text{C}$. **h**, Bulk sediment $\delta^{18}\text{O}$. Question marks in **a–d** denote absence of two to three samples because of the lack of suitable foraminifera for analysis in this interval. Grey shaded zones I and II as in Fig. 1.

Site 1218 for ~200 kyr immediately before the rapid two-step deepening associated with Antarctic glaciation (see figure 1 of ref. 4).

We cannot yet determine whether the C19r event is global in occurrence because of the coring gap at ODP Site 1218 and radiolarian clays and low sedimentation rates ($\leq 0.2 \text{ cm kyr}^{-1}$) at other key drill sites in the Equatorial Pacific¹⁷ and on Shatsky Rise²⁷. But it is distinct from the much longer-lived Middle Eocene Climate Optimum already documented at Site 1260¹⁸ and it is more similar in expression to the well-known intervals of rapid carbon-cycle-led global warming and CCD shoaling in the early Palaeogene. The magnitude of the palaeoceanographic signals that we have documented for magnetochron C19r at Site 1260 is smaller than seen at the Palaeocene/Eocene boundary^{3,10} but at least as large as those marking the Eocene Thermal Maximum 2 (~53 Myr ago)¹¹.

Our findings appear to highlight the instability of Eocene climate and to emphasize close coupling to the carbon cycle as expressed in oceanic carbonate saturation and $\delta^{13}\text{C}$. If the interval of CCD shoaling and isotopic shifts that we document is substantiated elsewhere, our results suggest that carbon-cycle-led instabilities akin to those documented in the early Eocene were not restricted to the Cenozoic climate optimum but also occurred millions of years later when the Earth's baseline climate had cooled substantially and was poised much closer to the threshold of continental glaciation (Fig. 1a). Climate modelling experiments suggest^{12,13} that this threshold would have been crossed earlier in the Southern Hemisphere than in the Northern Hemisphere (Fig. 1a) because of the fundamentally different land-ocean distributions at the two poles. Our work helps to realign the geologic record with this view.

METHODS

Chronology. We use the published²⁸ palaeomagnetic reversal stratigraphy for ODP Site 1260, which we supplemented by analysing nearly 100 additional samples collected at approximately 20 to 30 cm intervals across each of the magnetic reversals in the studied stratigraphic interval (magnetochrons C20r through C18r). Methods are as in ref. 28.

CaCO₃ and stable isotope data. All data were generated at the National Oceanography Centre, Southampton, UK. Bulk sediment weight %CaCO₃ was measured on small (20–30 mg) discrete samples (1–5 cm spacing), by high-precision coulometry. Our foraminiferal stable isotope ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) data were generated using species separates of the benthic and planktic foraminifera *Cibicidoides eoceanus* and *Morozovella lehmertii* respectively. Foraminifera were cleaned by ultrasonication before analysis. Benthics were picked from the size range 300–450 μm while planktics were picked from the 250–300 μm size fraction. Bulk stable isotope measurements were generated on splits of the same samples used for CaCO₃ data. All stable isotope measurements were determined using a Europa GEO 20-20 mass spectrometer equipped with an automatic carbonate preparation system. Results are reported relative to the Vienna Pee Dee Belemnite (VPDB) standard with an external analytical precision, based on replicate analysis of an in-house standard calibrated to NBS-19, better than 0.1‰ for $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$. Benthic $\delta^{18}\text{O}$ values that we report from ODP Site 1260 have been adjusted to equilibrium by adding 0.28‰ VPDB, the Palaeogene correction factor for *Cibicidoides*. We plot *Cibicidoides* data from ODP Site 1218 in the same way to aid comparison (Site 1218 data from *Nuttallides truempyi* are reported in the same way as in ref. 8).
